In parallel, Ayres offered an explanation for the out-of-character cool high-altitude gas. His 'thermal bifurcation' mechanism was an elaboration of the key role of CO surface radiative cooling—something like a reverse greenhouse effect—originally described independently by T Tsuji and H R Johnson in the context of the photospheres of red giant stars. The idea is as follows. The vibration–rotation transitions of CO very efficiently convert gas collisional energy into infrared photons. Those photons that escape the region carry away thermal energy and thus cool the gas. When there is little or no mechanical heating in the outer layers of the photosphere, the strong surface cooling in the 4.7 μm CO bands drives the gas to a low-temperature state, balancing the mild heating in the H^- continuum (optically thin absorption of mainly visible photons from the background photospheric radiation field). If a small amount of mechanical heating is introduced on top of the slight radiative component, however, the gas will warm and the CO molecules will begin to dissociate. The loss of CO reduces the cooling, leading to additional warming and further dissociation. The ensuing thermal runaway ('heating catastrophe') halts only above about 6000 K, where partial ionization of hydrogen liberates enough electrons to collisionally energize high-temperature cooling species such as Ca^+ and Mg^+. If the mechanical heating then is removed, the gas first cools down to the H^- boundary temperature ($\sim$4900 K), at which point CO begins to form, which cools the gas further; more CO forms, and so forth, leading to a 'cooling catastrophe' that returns the region to the low-temperature branch of the 'bifurcated' energy balance.

In this view, the outer atmosphere of the Sun can exist in two rather different thermal states—one cold, the other hot—depending on the amount of mechanical energy deposited locally. The thermal bifurcation mechanism naturally operates only at high altitudes; once the CO $\Delta v = 1$ bands become optically thick, the infrared photons are trapped in the source region and the radiative cooling is strongly suppressed.

In the thermal bifurcation picture, the classical hot chromosphere is confined to small-scale overheated structures bathed in a pervasive cool high-altitude layer close to radiative equilibrium. Figure 1 is a cartoon contrasting the historical and new views of the solar outer atmosphere.

Photosphere–chromosphere interface

The classical picture, illustrated in the left-hand panel, is a plane-parallel stratification; a hierarchy of distinct layers, controlled by different energy budgets, but through which the temperature runs smoothly. The layered atmosphere represents the idealized response of a hydrostatically

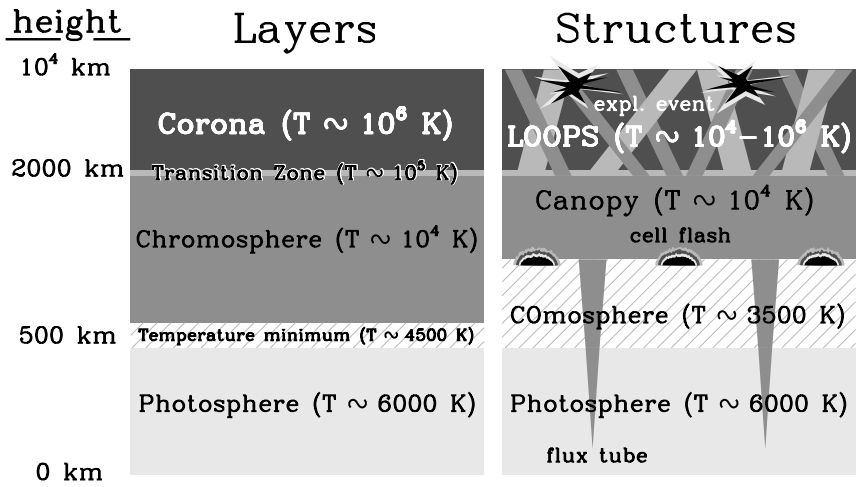

Figure 1. Classical and modern views of solar atmosphere. Height '0' is at $\tau_{500\ \mathrm{nm}} = 1$.

stratified gas in which the mechanical heating is uniform horizontally and varies slowly with height. The key layers and their interrelationships are described elsewhere in this volume.

The new paradigm—structures—is illustrated on the right-hand side of figure 1. It is not particularly new at all, but has been around in one form or another ever since the first high spatial resolution pictures of the chromosphere and corona were taken decades ago.

A jumble of magnetic fields—organized into a hierarchy of loop-like features—constitutes the CORONA. Its underside terminates in a canopy, occupying what previously would have been called the upper chromosphere (see CHROMOSPHERE: MAGNETIC CANOPY). The canopy itself is further rooted mainly in the supergranulation network by slender funnel-shaped flux tubes. These penetrate down through the photosphere into the convection zone, ultimately connecting to the deep source region of the magnetic flux (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES). Interactions between the tangled fields in and above the canopy give rise to localized explosive events traced by high-velocity jets in far-ultraviolet lines (see TRANSITION REGION: EXPLOSIVE EVENTS).

Much of the 'chromospheric' emission forms in the canopy, threaded by warm gas with large horizontal density contrasts. Additional contributions come from the downward extensions of the flux tubes, which evidently are hotter than the surrounding 'quiet' medium into at least the middle photosphere. A third component arises from cell flashes at the base of the canopy. These transient events are seen commonly in the interiors of the supergranulation cells. They are thought to be caused by outward-running acoustic disturbances that steepen and form shocks at high altitudes.

The canopy is ubiquitous and its density striations can be traced in Hα filtergrams. The cell flash and low-altitude flux tube components are compact, giving rise to transient and persistent bright points, respectively, in Ca K 393 nm spectroheliograms.

Between the upper photosphere ($h \sim 500$ km) and the base of the canopy ($h \sim 1000$ km) lies the COmosphere, the cool zone mentioned earlier, replacing what historically was designated the low chromosphere.

The essential aspects of the thermal bifurcation phenomenon were verified in the late 1980s in a series of *ab initio* model solar atmospheres constructed by L Anderson and R G Athay. The authors found that very low temperatures ($T < 3000$ K) are possible at high altitudes (dominated there by CO cooling); the CO-cooled zone can persist in the face of low-level mechanical heating but it disappears abruptly once the heating exceeds a critical level. At the same time, 2D radiation–hydrodynamic simulations of convection, with high-altitude CO cooling, by M Steffen and D Muchmore also demonstrated that the strong surface emission in the $\Delta v = 1$ bands can maintain a cold ($T \lesssim 3000$ K), horizontally uniform layer above the classical $T_{\min}$ in the face of the fluctuating granular radiation field and overshooting.

Beyond the Sun, the thermal bifurcation mechanism was recognized as one facet of the more general phenomenon of autocatalytic 'molecular cooling catastrophes'. These operate in a diversity of cosmic environments; for example driving the fragmentation and collapse of molecular clouds, or forging silicate grains in the bloated outer envelopes of red supergiants.

Current research

In 1992, inspired by the growing interest in infrared solar physics—not only the CO controversy but also the major benefits for magnetic field studies—the National Solar Observatory (NSO) installed a large infrared grating in the 13.8 m main spectrograph of the 1.5 m McMath–Pierce telescope. The mosaic grating, one of the largest in the world, was salvaged from the mothballed horizontal

infrared spectrograph where Noyes and Hall had carried out their pioneering observations of the CO 4.7 μm bands two decades earlier.

Off-limb emissions

In April 1993, on a day of particularly good seeing during engineering tests on the newly refurbished spectrograph, W Livingston of the NSO staff discovered the remarkable off-limb emissions of the CO lines.

The limb corresponds to the point on the projected disk of the Sun where the line of sight becomes transparent in the continuum; thus the background intensity falls away. The CO lines can be in emission beyond the continuum 'edge' if they still are optically thick along the raypath: the thermally radiating—albeit cool—CO lines shine against essentially dark sky. (On the disk, the glare of the hot continuum radiation causes the cool CO cores to appear in 'absorption'.) The observation showed directly that molecular gas must exist well above the altitude where conventional models place the chromospheric temperature inversion; simulations suggest that cool gas is present up to perhaps 1000 km.

Figure 2 depicts the off-limb emissions in the 4.67 μm region. The observations were obtained during the morning of 9 May 1996, under clear skies with moderately good seeing. They were acquired with a long-slit cryogenic camera system that superseded the single-channel scanner used by Livingston. The spectrograph slit was placed across the north limb, perpendicular to it. The figure represents the coaddition of the five sharpest spectrograms from a run of 1000 short exposures. The coadded frame was divided by an average on-disk spectral trace to normalize the intensities and suppress absorptions from the Earth's atmosphere.

The CO lines are the mounds of emission, extending beyond the bright continuum edge, in figure 2 (top); each 'bump' corresponds to an individual CO transition, all observed simultaneously, at the same point on the limb. Figure 2 (bottom) depicts the translimb extensions, measured bin by bin across the spectrum; '0' refers to the apparent continuum edge. Although the maximum displacements in the cores of the strongest CO lines ($\sim 0.7''$) are only about half the effective instrumental resolution (because of seeing, diffraction and scattering), they can be measured accurately relative to the continuum. (In the same way that tiny parallaxes—hundredths of an arcsecond—can be measured on plates with spatial resolution no better than 1 arcsec.)

The off-limb CO emissions are built up along an enormous pathlength through the low chromosphere. They tell us directly that there is some cool gas present somewhere along the sightline, but not where or how much. The key question is how widespread the cool gas truly is.

Surface maps of temperature and velocity

By sequentially stepping the McMath–Pierce telescope, the new long-slit camera system allows one to build up strip-maps of key CO line parameters: central absorption intensity (related to surface temperature), Doppler shift (a measure of line-of-sight velocity) and line broadening (tracing local turbulence). The spatial scanning can be done repetitively to make 'movies'.

First use of the new system for spectral imaging of CO was in October 1993 by H Uitenbroek, R Noyes and D Rabin. Additional CO thermal and velocity mapping was conducted by T Ayres and D Rabin the following spring. Both studies concluded that the evident patchwork quilt of spatial variations in the CO brightness is associated mostly with the oscillation interference pattern, particularly at high altitudes (i.e. in strong CO lines). Occasional persistent CO 'bright points' were seen, coincident with Ca K network fragments (regions of strong magnetic field arrayed along the stagnation points of the large-scale horizontal flow pattern of the supergranulation). There was no evidence in either study for a significant population of very dark points. That absence constrains alternative explanations for the anomalous limb-darkening of the CO bands.

How pervasive is the cool gas?

To reproduce the extreme-limb darkening and off-limb emissions of the CO line cores requires either (1) cool material with a high filling factor (say, $\sim$80%) at high altitudes or (2) a smaller covering fraction (say, $\sim$20%) of much colder structures. In the first case, the intensity behavior is controlled everywhere by the pervasive cool component, and an image looking straight down on the solar surface should appear relatively bland and featureless, apart from the relatively small fluctuations due to the p-mode pattern. In the second case, the isolated cold, but transversely opaque, 'pillars' dominate only near the limb where they effectively 'shadow' any hot structures (the latter naturally are transparent in CO). At disk center, however, the cold regions (with $\Delta T \sim 1000$ K) should show up as small-scale 'dark spots' with the $\sim$20% filling factor. So far—within the sustained few-arcsecond resolution encountered under good conditions at Kitt Peak—nothing remotely like the expected sprinkling of dark points has been seen. The opposite scenario—pervasive COmosphere—thus appears to be more promising.

Dynamical COmosphere?

An alternative view of the COmosphere has been proposed by M Carlsson and R F Stein. One-dimensional radiation–hydrodynamics simulations suggest that the 500–1000 km altitude range might be in a continually evolving thermal state owing to the passage of steepening acoustic wave-trains from below. At those low densities, the CO chemical formation timescales are long. The molecular population cannot respond to the instantaneous temperature perturbations, but instead attains an equilibrium based on the time-average thermal profile (rather cool in the Carlsson and Stein model). Such a steady-state background of CO, existing in a fluctuating thermal environment, might be

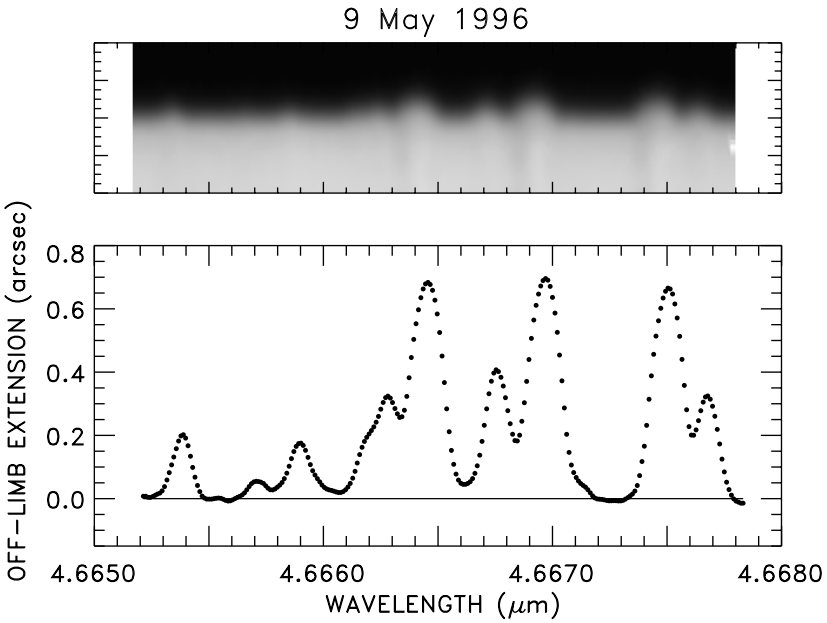

Figure 2. Off-limb emissions of CO lines.

capable of explaining the off-limb emissions and extreme-limb darkening of the infrared $\Delta v = 1$ lines. At the same time one would record significant time-averaged ultraviolet signatures from the same spatial volume (mostly from the high-temperature peaks, owing to the exponential sensitivity of the thermal emission (planck function) at short wavelengths).

A second dynamical explanation has been offered by H Uitenbroek and R Noyes. They suggest that the COmosphere is a byproduct of the expansive cooling of convective granules overshooting into the stable layers of the high photosphere.

The observational consequences of these proposals should be pursued further. In addition, the CO chemistry (and cooling) should be incorporated in the dynamical simulations.

Implications

In the final analysis, the COmosphere very likely is a relatively passive zone of the outer atmosphere, really just an outward extension of the photosphere. Its importance comes in how one attributes the radiative activity of different levels of the atmosphere in a global assessment of the energy budget. The gas density is large in the 500–900 km range compared with the higher-lying canopy zone. Because the radiative cooling depends on $\sim n^2$, the intermediate altitude range plays a strategic role in the energy budget. One can imagine that a calculation of total radiative losses (which must balance the input heating, and therefore are a proxy for it) will yield very different answers if there is a temperature *rise* in those layers (classical chromosphere) versus a temperature *drop* (COmosphere). If the thermal model is biased, gross errors in the inferred mechanical energy input are possible. (The source of the chromospheric heating is a longstanding mystery in solar–stellar physics.)

Finally, it should be mentioned that thermal bifurcation effects are relatively weak in G-type stars like the Sun and probably absent among the even warmer F types. That is because at a critical $T_{\rm eff}$, a few hundred kelvins hotter than solar, the H^- boundary temperature becomes too warm for a seed population of CO molecules to form and trigger a cooling cascade. Conversely, the mechanism becomes increasingly important toward the later spectral classes, especially prominent among the cool, low-gravity red giants.

Summary

The stratification of the solar atmosphere once was thought to be well understood, based on a wealth of ultraviolet and optical diagnostics. Over the past two decades, however, studies of infrared molecular spectra have unearthed troubling anomalies. Strong lines of the 4.7 μm fundamental bands of carbon monoxide display very cool brightness temperatures at the extreme limb and curious off-limb emissions protruding hundreds of kilometers into the supposedly hot chromosphere. A straightforward—but controversial—proposal is that the low chromosphere is not hot at all, but instead is permeated by CO-cooled 'clouds', a COmosphere, if you will.

Circinus

(the Compasses; abbrev. Cir, gen. Cirini; area 93 sq. deg.) A southern constellation which lies between Centaurus and Triangulum Australe, and culminates at midnight in early May. It was introduced by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2.

A small, inconspicuous constellation, the brightest stars in Circinus are α Cirini, a binary with white (F1) and orange (K5) components, magnitudes 3.2 and 8.6, separation 15.7″, and β Cirini, magnitude 4.1. Other interesting objects include NGC 5315, a tenth-magnitude planetary nebula.

Circumpolar Stars

Stars that never set as seen from a particular location. The requirement for this to happen is that the star's polar distance is less than the observer's latitude—thus from a location in latitude 52° North, stars of NPD less than 52° (i.e. with declinations of between 0° and +38°) are circumpolar and will be seen to circle around the north celestial pole. In practice it is difficult to observe objects very close to the horizon, so a more realistic requirement would be for the star's polar distance to be at least 5° less than the latitude. Observed from the Earth's geographical poles all stars are circumpolar, whereas from the Equator none are circumpolar. Circumpolar stars transit the meridian twice a day, at upper and lower culmination alternately.

Clarke, Arthur C (1917–)

Science fiction writer and space visionary, born in Minehead, Somerset, England. Worked during the second World War on radar ground controlled approach equipment, became president of the British Interplanetary Society. In 1945 he wrote a paper 'Extra-terrestrial relays' which described the principle of satellites in geostationary orbits. The geostationary orbit at 42 000 kilometers has been named *the Clarke orbit* by the International Astronomical Union. Clarke inspired satellite applications for weather forecasting. He developed the concept of the rotating space station, pictured by Stanley Kubrick in the movie *2001: A Space Odyssey*, scripted by Clarke.

Classification of Stellar Spectra

How does a scientist approach the problem of trying to understand countless billions of objects? One of the first steps is to organize the data and set up a classification scheme which can provide the best insights into the nature of the objects. Perception and insight are the main purposes of classification. In astronomy, where there are 'billions and billions' of stars, classification is an ongoing process, with new discoveries either being incorporated into the classification scheme or remaining isolated as peculiarities worthy of further study. With new telescopes and new detectors opening fresh windows to the universe, the need for classification is likely to persist as an essential ingredient of astronomical progress.

If we were able to travel quickly among the stars, we would notice their size, color and surface brightness first. Being earthbound, we can see only the Sun in detail, but there are many different criteria which we can use to classify stars and other objects: position, brightness, polarization, color, spectrum, surface brightness, movement and variability. Of these, the spectrum yields the most information about the nature of the star.

Astronomy is not an experimental science, stories of alien abductions notwithstanding. Unlike most scientists, astronomers are limited to observations from a distance. Stars and galaxies cannot be heated over a Bunsen burner; chemicals cannot be added to a star in order to learn from the reaction. Cosmic experiments do occur, but the timing is serendipitous, so the observer must be patient and watch, with no choice over the parameters of the event. To maximize the chances of catching a cosmic experiment, large surveys of stars and galaxies have been and will be conducted.

Because of this need to organize large sets of observational data, a sophisticated classification philosophy was developed by W W Morgan at the Yerkes Observatory of the University of Chicago, and was given the title 'The MK process'. Interestingly, the astronomical development anticipated the thinking of the Bavarian philosopher, Ludwig Wittgenstein, on the subject of the use of specimens in classification (Wittgenstein 1953).

The most important function of a classification system is to provide a general reference frame into which most objects to be studied can be fitted. Statistics based on the classification scheme can provide powerful insights into the nature of the objects under consideration. Trends can be observed among the normal objects and rare or pathological objects can be identified easily. Isolating peculiarities is also important in astronomy, because the detailed study of peculiar stars often provides new insight into the nature and behavior of normal stars. Classification is the root of our understanding of stars and STELLAR EVOLUTION.

In addition to the development of a general reference frame and the discrimination of peculiar spectra, classification techniques can be used very successfully for the determination of distances to stars. Although the method is referred to as 'spectroscopic parallax', the name is misleading because the technique does not use actual trigonometric PARALLAXES directly. It is based on the assumption that *stars with similar spectra have similar fundamental parameters*. This assumption allows astronomers to use nearby stars with good trigonometric parallaxes to provide a calibration which can then be applied to distant stars with similar spectra. Until recently, moderately hot or large stars, which are among the apparently brightest stars because of their intrinsic luminosity, but which are actually much more rare per unit volume than stars like the Sun, had no counterparts near enough in distance for the technique of trigonometric parallax to be effective, so indirect methods were developed. The indirect methods include the use of DOUBLE STARS and STAR CLUSTERS for bootstrapping from common stars with known distances to the uncommon hot, HIGH-LUMINOSITY STARS by assuming the same distances for the members of a cluster. Using data from the astrometric satellite HIPPARCOS, it is now possible to extend the distance calibrations by a factor of 10, which allows direct calibrations of red and yellow giant stars as well as many of the stars hotter than the Sun; however, the supergiants and the hottest stars are still beyond the reach of high-quality trigonometric parallaxes. For the luminosity calibration of these rare but luminous stars, binary and cluster-fitting techniques are still used.

The process used for classification is comparison of the unknown spectrum with the known spectra of well-studied standard stars (specimens), using pattern-recognition techniques involving all the features in a stellar spectrum. When good-quality spectra are used, and the unknown star is carefully compared with a good set of standard stars, it is possible to obtain very reliable and informative results. Poor results are usually due to an inadequate or inappropriate grid of standard-star spectra.

The history of classification of stellar spectra

Father ANGELO SECCHI (1818–78), a Jesuit astronomer working in the 1860s at the Vatican Observatory, was the first to provide a general classification scheme for stellar spectra. He looked at thousands of stars with a visual spectroscope and small telescopes (15–25 cm aperture), but his observations were not photographic, so the blue–violet region of the spectrum was not prominent, mainly because the human eye is not very sensitive to deep blue wavelengths. The coolest stars dominate his classification scheme, forming two of his four classes, partly because they are among the apparently brightest stars in the visual region of the spectrum, and partly because of the striking appearance of their molecular bands. In modern terms, his four classes are

I. stars hotter than the Sun,
II. stars like the Sun,
III. stars cooler than the Sun with titanium oxide absorption bands in the yellow and red regions of the spectrum, and

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

IV. stars cooler than the Sun with carbon molecular absorption bands in the yellow and red regions of the spectrum.

The class IV stars are easily distinguished from class III by their redder color, by the positions of the bands and by the appearance of the carbon bands, which fade in the opposite direction from those of titanium oxide.

By the end of the 19th century, Edward C Pickering and others realized the importance of photographic spectra and objective-prism telescopes for classifying very large numbers of stars using a uniform scheme with consistent criteria. The 'HD' project at Harvard College Observatory was sponsored by Henry Draper and carried out primarily by ANNIE JUMP CANNON, who by the mid-1920s had classified more than a quarter of a million stars on a homogeneous, one-dimensional system. The HD system, which now corresponds more or less to the temperature scale of modern astronomy, originally was based chiefly on the strength of the hydrogen lines and types were assigned in alphabetical order: A, B, C, ... Later, when it was discovered that the hydrogen lines reach a maximum strength (A-type stars) at temperatures lower than those of B-type stars and O-type stars, and that some of the letters are redundant, the sequence of letters was changed to the order used today for the temperature reference frame: OBAFGKM(SRN). The SRN types are in parentheses because their temperatures are parallel to the GKM stars, the spectra differing in chemical composition rather than temperature.

There are various mnemonics devised for (and by) students to help remember the sequence, but the most common is 'Oh, Be A Fine Girl (Guy), Kiss Me Sweetly Right Now'. Dr Nancy Houk, at the University of Michigan, is reclassifying all of the HD catalogue stars on the two-dimensional MK system. The results of her work in the first four of six volumes are shown in figure 1.

Also at Harvard, Antonia Maury isolated a class of peculiar stars which she classified with a lowercase 'c' placed in front of the temperature class. Her important insight formed the basis of the second dimension, which corresponds to surface gravity and is related to the luminosities of stars.

Many other systems have been proposed, but most of them are intended for the classification of stars in particular regions of the HERTZSPRUNG–RUSSELL DIAGRAM and are used to advantage only in that part of the HR diagram. The BCD system of Barbier, Chalonge and Divan, which measures the Balmer jump directly, is a good example; it is powerful for its purpose, but is not good as a general reference frame. Others for a variety of reasons have not achieved wide acceptance. The Mount Wilson system developed by Adams in the 1930s is another example; in that case the calibration was used for the classification, so the parameters changed whenever a new model was introduced. Adams' system became very cumbersome and inefficient. For further historical examples, see the article by Kurtz in *The MK Process* (Garrison 1984) and the excellent history of spectroscopy by Hearnshaw 1986: *The Analysis of Starlight*.

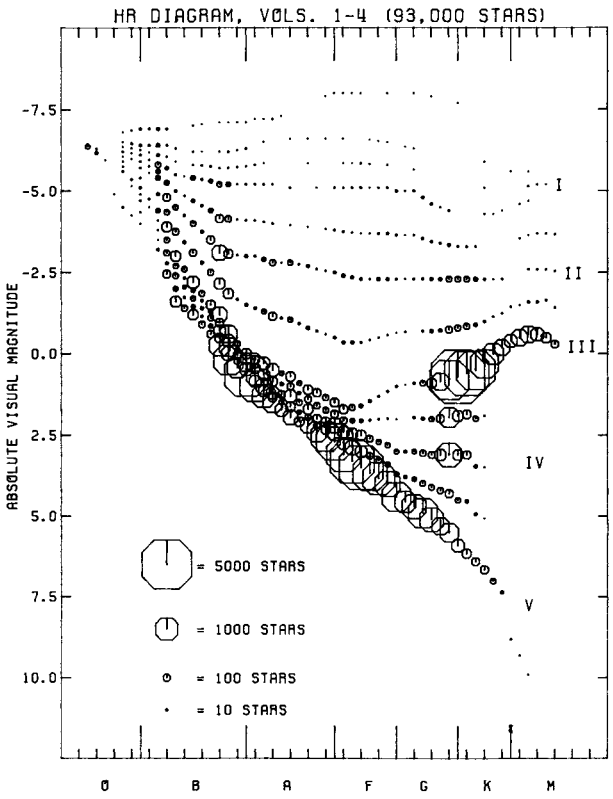

Figure 1. Hertzsprung–Russell (HR) diagram for all the stars contained in the first four of six volumes of the Michigan Spectral Catalog, a massive undertaking by Nancy Houk. It is an illustration of how MK spectral types can be used as a general reference frame to study the characteristics of stellar populations.

At the University of Chicago's Yerkes Observatory in 1943, W W Morgan, P C Keenan and E Kellman proposed a system of classification of stellar spectra known as the 'MKK system'. The 'MK system' (revised by Morgan and Keenan in 1953 from the MKK) is virtually the only one in wide use today as a general reference frame. Its success is due in large part to the philosophy of classification developed by W W Morgan—the MK process, of which the MK system is a subset. The general reference frame for the MK system is illustrated in figures 2 and 3.

The MK system

Classification systems are created for a reason. In using a particular system, it is important to be aware of why it was created, how it was constructed, what its useful limits are, how it has evolved and what credibility it has achieved. Collectively these correspond to the mandate of the system. The mandate of the MK system is to describe the blue–violet region of the spectrum of a star in terms of a set of standard stars, without reference to photometry, theory or other information.

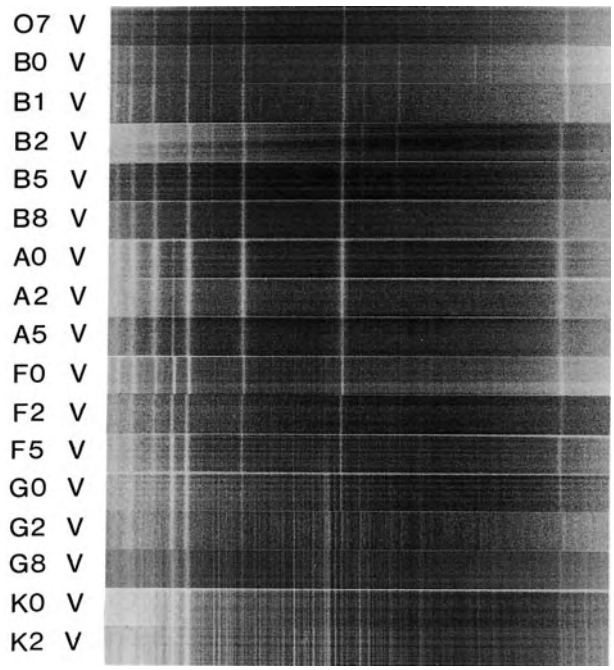

Figure 2. Montage of photographic spectra of standard stars illustrating the temperature classes for stars along the main sequence of the HR diagram. The sense of the sequence is that the O-type stars are hot and the K-type stars are cool. Notice that there are considerable differences in pattern along the sequence. Temperature is the primary variable in stellar spectra.

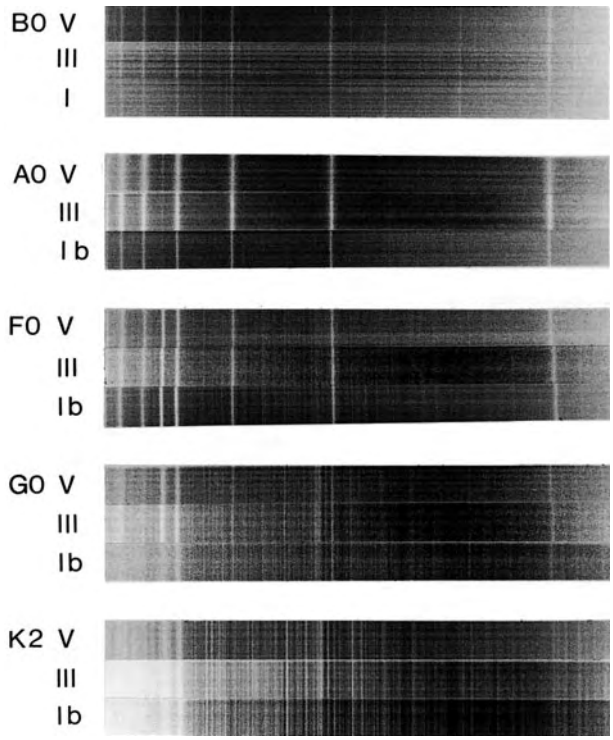

Figure 3. Montage of photographic spectra of standard stars illustrating the luminosity class sequences (V, III, I) for key spectral types (B0, A0, F0, G0, K0). The sense of the luminosity class sequence is that class I is brightest and class V is faintest for a given spectral type. Notice that the differences among the luminosity classes are somewhat more subtle than those for the temperature types, but are still quite easy to distinguish.

The value of the separation of the MK system from photometry and theory initially is that, at the interface between any two independent systems, there is information which is lost if one system is allowed to influence another. It is much more productive to compare two autonomous systems, assuming that both are carefully done, than to declare one or the other superior. For example, there is not a one-to-one relationship between the photometry and the spectrum, although, in general, the systems are correlated and can be used for a calibration. Another example is theory, which involves many simplifying assumptions and is continuously evolving (as it should). In this case, the derived parameters change with new advances in the models, so it is best not to mix the theory and the classification *a priori*.

The use of line-strength ratios helps with the comparison of spectra and enables a high level of discrimination of spectral types and luminosity classes. The MK system uses the following nomenclature.

(a) The Harvard sequence (OBAFGKMSRN) is retained for the major divisions of the temperature axis (figure 2), in order to preserve some continuity with the great work of the Henry Draper Catalog. O-type stars are the hottest and most massive, whereas M stars are the coolest. We know now that the carbon (R and N) stars are approximately the same temperature as the G, K and M stars except that the ratio of carbon to oxygen is reversed and that the S stars have similar temperatures to the M stars except that they show ZrO absorption bands.

(b) Each letter is followed by subdivisions 0–9, except for the O-type stars for which O3 is the hottest type.

(c) A luminosity-related class is added, representing indirectly the absolute brightness of the star, as indicated by features sensitive to surface gravity and microturbulence. Roman numerals are used to represent the luminosity class, with the sense that supergiants are I, giants are III and main sequence stars (called dwarfs, although they are similar to the Sun) are V (figure 3). Sometimes the subdivisions a, ab and b are used to refine the luminosity classification in the sense that ab is the middle of the box and a is among the brightest stars in the box.

(d) There is no single third dimension representing abundance because, in peculiar stars, elements can be individually affected. Thus the peculiarity is noted by the element's symbol (Fe, Ba, C, CH, CN, etc), followed by a number 1–5, which is positive for overabundance and negative for underabundance.

(e) When there are enough specimens in a peculiar class, the definition of 'normal' may be expanded to include them. This happened with supergiants, rapid rotators, emission-line stars and others. Thus, there are several additional symbols used in the classifications. A few examples will illustrate the principles. Rapid rotators are designated by the letters n or nn, depending on the rotation rate. Stars with hydrogen lines in emission are labeled with the letter e, which signals a detailed description of the star's spectrum in the notes; since emission lines are usually variable on time scales of years, the details are not given in the general spectral type but rather in the notes, accompanied by the date. Hot, O-type stars with helium, carbon, nitrogen or oxygen in emission are marked with the letter f. Very hot stars losing mass at a prodigious rate are classified as WOLF–RAYET (WR) STARS.

(f) If a star does not fit into the system at all, it is given the designation of the standard specimen which matches it most closely and the letter p is attached, indicating a peculiar (and probably especially interesting) star. The peculiarity is then described in a note.

(g) Typical examples of classifications are as follows: G2 V (the Sun's classification), indicating a star of moderate temperature and mass which is in the stable hydrogen-fusing stage of its life; M6 IIIe, indicating a cool giant star with hydrogen emission which is probably fusing helium into carbon for energy, and B0 Ib (close to the classification of the star which later became supernova 1987A), representing a very hot, large, very massive star which is evolving rapidly (astronomically speaking); K0 IIIb Fe2, CH1, CN−2 signifying a moderately cool giant star, slightly less luminous than most giants, with strong metals (Fe2), somewhat strong G-band (CH1) as well as weak CN; A5p (Cr, Eu) describing a moderately hot star with strong lines of chromium and europium.

The MK process

The success of the MK system is due mainly to 'the MK process', an Aristotelian, inductive approach to classification in general, which is based on particular specimens (standard stars in the case of stellar spectra) and is independent of calibrations from theory or photometry. It is not based on theoretical models or averages as in a Platonic approach, but it is autonomous and is based on existing objects. The classification of a stellar spectrum is a description in terms of the set of standard stars, so the actual classification remains the same when the calibration changes owing to advances in photometric techniques, the theory of stellar atmospheres or other methods of determining temperature, surface gravity, atmospheric structure or chemical composition. Each classification box is represented by one or more specimens rather than by its physical parameters. For example, the standard star α PsA = HD216956 represents the box A3 V in the MK system. The spectrum of an unclassified star is compared carefully with that of the standard star and determined to be *like* or *not like* α PsA. If it is *like* α PsA, it is given the classification A3 V; if it is *not like* α PsA, it is compared with another standard star and the process continues until a match is found. This is not as tedious as it seems, because a quick perusal of the spectrum of the unknown star will tell the experienced observer (or a computer program) which group of standard stars is most likely to match. A current calibration of the box, based on the calibration of the standard stars, is then applied to determine the physical parameters for the unknown star. With the large number of stars which have been classified, it would be a nightmare to have to redo the work every time new physical data become available. The value of an autonomous classification methodology is that, when the calibration changes from year to year or person to person, the classification does not have to be redetermined.

The MK process methodology outlines a way to extend the MK system beyond its wavelength definitions and standards. New autonomous systems, independent of the MK system and of each other, can be created to cover new categories of objects in and beyond the Milky Way Galaxy.

New wavelength regions: extending the classification

The general reference frame for MK types is the blue–violet region of the spectrum, which was dictated originally by a combination of the old prism spectrographs which cut off the ultraviolet (UV) and the relative insensitivity of yellow, red and infrared (IR) emulsions in the 1930s. Even today, with satellites, high-UV-throughput instruments and CCDs which are very sensitive in the red and IR, the blue–violet remains the best choice for a general reference frame, because it contains many lines and bands with a wide range of excitation. For particular classification problems in particular parts of the HR diagram, however, it is often a great advantage to use other wavelengths.

The energy distribution for the hottest stars peaks in the UV where there are strong lines suitable for classification of O- and B-type stars. Classification criteria and atlases have been published by NASA astronomers Janet Rountree and Nolan Walborn. The UV spectra are influenced strongly by stellar mass loss (winds) and the assumption is made that mass loss is correlated with the luminosity of the star, which is not always strictly true; there are exceptions. Also, cool stars do not have much light in the UV, and their UV spectra are dominated by chromospheric lines. Thus, the UV can be used advantageously for particular projects involving hot stars but is not good as a general reference frame.

The energy distribution for the coolest stars peaks in the IR and falls off rapidly toward the blue–violet. The IR is the best region for molecular bands, which are the most useful criteria for cool stars. This is an advantage for classifying the temperatures of cool stars, but there are very few atomic lines in the IR and lines from the terrestrial atmosphere interfere strongly. Blue spectra are needed

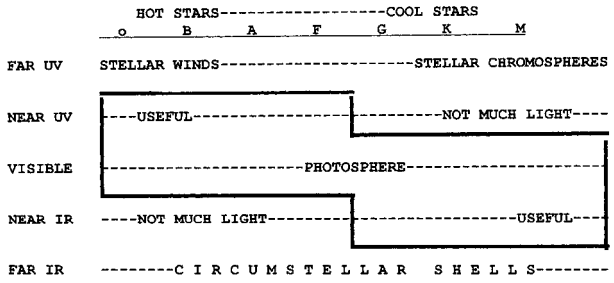

Figure 4. Table summarizing the choices of wavelength regions, as well as some of the general advantages and disadvantages for the various types of stars.

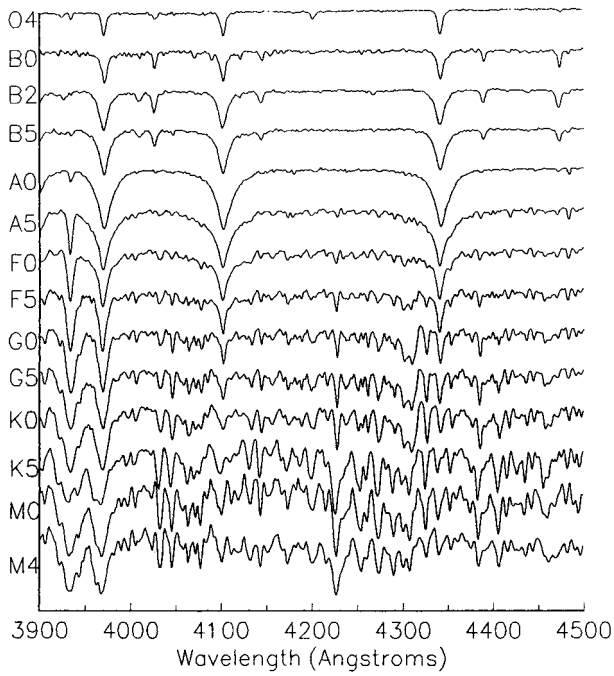

Figure 5. Similar to figure 2, but digital data have been used. The digital spectra cover a comparable wavelength region and have signal-to-noise ratios equivalent to those of the photographic spectra. The sequence of standard stars is an illustration of the spectral variations due to temperatures, for stars on the main sequence.

to properly determine the metallicities because there is much more variety of atomic lines of various excitations. Hot stars have less energy in the IR and the spectra are influenced strongly by circumstellar matter. Thus, the IR can be used advantageously for particular problems involving cool stars but is not good as a general reference frame. See figure 4 for a summary.

The digital dialect

Most pre-1980 classification atlases were photographic, but most of the work since then has been digital. CCDs are now used universally. There are some differences in use of the two media; however, the problems unique to the digital revolution have been worked out. Whereas photographic spectra are logarithmic (density) and two dimensional, digital spectra are linear and are usually represented as one-dimensional tracings (figure 5). In pattern recognition, the eye prefers to look at surfaces rather than line tracings. Digital detectors are much more efficient than photographic emulsions, although observers often underestimate the overall photographic signal-to-noise ratio (S/N) in determining equivalent digital S/N. The best widened photographic spectra used for classification have S/N of approximately 200–300, so the digital equivalent of the best photographic work should be similar. Many observers work with much less, and the accuracy of their results suffers. However, when working with extremely faint objects, it is necessary to compromise. Good digital classifications are possible with $S/N = 50$ and mediocre ones with $S/N = 35$, but below that the results are likely to be unreliable.

Another difference in approach is in the process of comparison with standard stars. Because of the non-linearity of the photographic process, the exposures (i.e. S/N) for the standards had to be similar. However, with linear digital data, it is advisable to take the bright standards at very high S/N (several hundred) even if it is only possible to take the unknown at very low S/N.

With digital data, care must be taken to prevent loss of information or introduction of false information during the reduction process, especially during rectification. Also, when comparing tracings, it is important to use ratios of close lines and to look at the line strength rather than the sharp bottoms of the lines, because, for strong lines, the bottom of the line is at lower S/N and the wings of the lines are far more reliable and important. Thus, digital data, while much more efficient, versatile and easy to work with than photography, must be used with care to give superior results.

Automating the classification process

The tradition in MK spectral classification involves comparing visually the entire blue–violet spectrum of a star to find a match with one of the standard stars. Humans are very good at pattern-recognition, which is difficult for computers. However, powerful computer techniques have been developed for automation by simulating the pattern-recognition process. (For a review, see the article by Kurtz in Garrison (1984).) The most successful methodologies, which allow computers to do as well as or better than humans on normal stars, are the minimum metric distance (MMD) and neural net (NN) approaches. Each has advantages and each has been tested on large data sets. Automation techniques can be applied to great advantage when dealing with data sets of millions of stars. In such cases, when new types of peculiarities are found, they are flagged for human consideration. This means not only that very large numbers of stars can be classified but that human experts still will be needed to interpret the results.

Natural groups

The MK system was set up to be used with spectra of high enough resolution to permit detection of the most important peculiarities, yet low enough to reach stars as faint as possible. This compromise is satisfied in the range of resolution 0.1–0.3 nm. There are situations, however, when it would be useful to have some information for stars as faint as possible, which would mean extending the MK process to lower resolutions. W W Morgan developed the concept of natural groups, which uses the strongest, most outstanding features of the spectrum to identify uniquely particular types of stars, even at extremely low resolutions. Examples are the A0 V stars, whose hydrogen lines are stronger than in any other normal type of star and can be detected at resolutions as low as 2–3 nm. Thus if the hydrogen lines are still visible when a spectrum's resolution is degraded to this amount, the star must be approximately A0 V. At very low (e.g. 3 nm) resolution the G8–K2 III stars are uniquely outstanding, because their temperatures and surface gravities are optimum for peak visibility of the broad CN bands. Similarly the coolest stars can be classified uniquely and easily at very low resolution by use of their TiO and VO bands in the red region of the spectrum and their CO bands in the IR domain. The powerful techniques of natural groups can thus be used as an initial filter to define a set of objects for further study but are not good for definitive types for individual stars because the three regions mentioned happen to be also the locations of many peculiar and interesting stars whose peculiarities are not visible at such low resolutions.

Integrated spectra: binaries, clusters and galaxies

The concept of natural groups also can be used to disentangle the complexities of integrated spectra of binary stars, globular star clusters and galaxies. If, for example, the CN bands are strong in the integrated spectrum of a galaxy nucleus, there must be a substantial contribution to the light by G8–K2 giant stars. MgH is a molecular band that is prominent only in cool dwarfs; if it is not visible in the integrated spectrum, the cool dwarfs must not be present in enough numbers to counteract the light from the giants, which, while much rarer, are also much more luminous. W W Morgan and his associates carried the idea to the limit, using extremely low resolution (1000 nm mm^{-1}), which produced spectra that resembled tadpoles. The Cyg OB6 Association was discovered using the tadpoles to reveal highly reddened, very faint, massive, hot stars, which were distinct from cool stars with similar colors. These natural-group techniques have not been fully exploited in the interpretation of the stellar content of clusters and galaxies.

Objective prisms, multiobject spectrographs and surveys

Taking individual spectra for large surveys is very time consuming. One way to improve efficiency is to use a wide-field SCHMIDT TELESCOPE fitted with a thin prism across the aperture, thus producing spectra of all the stars in a large area. In the early 1900s, Annie Jump Cannon used objective-prism spectra for assigning spectral types on the Harvard system to more than a quarter of a million stars over the entire sky. Dr Nancy Houk's reclassification of all the Henry Draper stars on the two-dimensional MK system is also based on objective-prism spectra.

Fiber optics are being used to obtain many spectra of faint objects simultaneously. Modern multiobject spectrographs can be used to take low-dispersion spectra of hundreds of stars or galaxies at a time, yielding thousands of spectra per night. Automated classification techniques could be used to great advantage by providing preliminary, on-line spectral types for the stars and signaling the observer when unusual spectra are detected (e.g. a supernova in a distant galaxy), but this idea has not been explored effectively yet.

Calibration: effective temperature, logarithm of gravity and abundances

The MK process is inductive. The classifications are based on a set of standard stars only and are independent of the results of theory, photometry, all other external influences. After the classifications have been performed, it is useful to calibrate the system, to tie it into the other methods as well as the fundamental parameters of $T_{\rm eff}$, log g and [Fe/H].

An autonomous approach such as the MK process is useful because there is information in the interface which would be lost if the methods were not *a priori* independent. With the new data from satellites such as HIPPARCOS, it is then possible to calibrate the luminosities for nearby stars and thus to obtain distances for all stars with similar spectra. The theory of STELLAR ATMOSPHERES can be used to calibrate spectral types, luminosity classes and abundance indicators in terms of the fundamental parameters of $T_{\rm eff}$, log g and abundances of key elements.

The principle of complementarity

When comparing the results of various approaches to the interpretation of stellar spectra in terms of the fundamental parameters such as $T_{\rm eff}$, log g and [Fe/H], it is most productive to think of the methods as complementary, with important information in the interface. For example, while there is general agreement between the carefully measured colors of a star and its spectrum, there is not a one-to-one correlation between photometry and the spectrum, mainly because they refer to different parts of the stellar atmosphere. The photometry refers primarily to the bottom of the photosphere, whereas the spectrum arises from several layers of the photosphere. Different results from the two techniques might indicate a peculiar structure in the atmosphere. If both techniques have been used carefully, there is usually a good reason for the difference and many types of peculiar stars have been discovered through the disagreement between their colors and their spectra.

Summary
An inductive process of classifying stellar spectra has been outlined. With careful attention to comparison with standard specimens, a high level of discrimination can be achieved. The MK process is a powerful tool for astrophysical insight. W W Morgan, creator of the MK system of spectral classification, has written 'It could be said, with some truth, that the spectral forms have helped to classify themselves, by showing where they are most comfortable'.

Clavius, Christoph (1538–1612)

Mathematician, born in Bamberg, Germany. Became a Jesuit in Rome, and wrote a number of textbooks, including a version of Euclid's *Elements*, a commentary on the *Sphere* of Sacrobosco, and books on algebra, the astrolabe, and practical arithmetic and geometry. He participated in the commission for the reform of the calendar that led, in 1582, to the institution of the Gregorian calendar. In his astronomical books, he opposed the Copernican system on both physical and scriptural grounds, but at the end of his life he was faced with telescopic observations by GALILEO, which he was able to repeat, of the phases of Venus and the satellites of Jupiter. He certified what Galileo had seen as real and called on astronomers to consider how the celestial orbs may be arranged in order to save these phenomena but could not bring himself to abandon the Ptolemaic view.

Clementine

Joint project between the US Strategic Defense Initiative Organization and NASA, launched in January 1994. Designed to test military sensors and spacecraft components in the space environment. Also intended to make scientific observations of the Moon and near-Earth asteroid 1620 Geographos. Obtained global ultraviolet and infrared imaging, laser ranging altimetry coverage from 60° S to 60° N, and charged particle measurements. Obtained the first data to indicate the presence of water ice inside permanently shaded craters at the lunar poles. Failed before it could reach Geographos.

Climate

Earth's climate may be defined as the global physical condition, averaged over some period of time (typically decades or longer), of the EARTH'S ATMOSPHERE, OCEAN and ice sheets. It is the presence of a relatively dense atmosphere—third among the solid bodies of the solar system—that makes Earth habitable. Without the blanketing of infrared energy radiated from Earth's surface and lower atmosphere, conditions would be well below freezing almost everywhere around the globe. While the atmosphere is the most immediate and palpable part of the Earth's climate system, at least to land-based life, the ocean plays a crucial role. The ocean and atmosphere exchange heat and water vapor (as well as carbon dioxide and other gases). The much greater mass of the ocean compared with the atmosphere provides a damping effect on the climate system, but paradoxically might also drive it from one particular state to another (for example from glacial to interglacial climate). This dual role of the ocean is a consequence of the presence of ocean currents, which in turn depend on the distribution of heat and salt (salinity) with location and depth. Absent our deep oceans, Earth's climatic regime would be drastically different from the present state and past states recorded in the geologic record. Ice sheets also play a role in strongly reflecting the Sun's energy and in storing fresh water that when melted changes the ocean's salinity and global sea levels.

The primary energy source for the climate is the Sun. Rotation of the Earth, seasonal variation of the polar orientation and long-term orbit changes all serve to modulate the amount of solar energy received from place to place and on various timescales. Despite rather dramatic variations in climate through history, a remarkable fact derived from the geologic record is the essential stability of liquid water over large parts of the Earth's surface at least back through 4 billion yr ago. The mass and energy exchanges between the various components of the climate system, and indeed their interactions with the crust of the Earth, must have maintained this essential stability in the face of large progressive changes in the energy output of the Sun implied by stellar evolution theory. The habitability of the Earth is therefore far more complex than simply its favorable position some 150 million km from the Sun.

Worldwide monitoring of the climate has been possible only in the last few decades owing to improvements in transportation, instrumentation and information-transfer technologies. Direct measurements, i.e. *in situ*, represent the first kind of climate data to be collected, and include pressure, temperature, water content (humidity), wind speed, salt content (at oceanic sites), cloud and precipitation conditions. Surface stations grew in number from about 60 in 1875 (which were primarily in the United States and Western Europe) to about 7000 stations reporting daily today. Upper-atmosphere data are more difficult to collect, but by the late 1980s about 800 stations (mostly near airports) launched balloon-borne packages ('rawinsondes' or 'radiosondes') twice daily to measure meteorological parameters at altitudes up to 30 km.

Satellite monitoring began with the launch of TIROS 1, the first satellite designed specifically for weather observations, in 1960. In the ensuing four decades monitoring of cloud and precipitation patterns by orbiting satellites has become an established part of weather and climate studies and has expanded to include remote observations of atmospheric chemistry, atmospheric energy balance, sea state and many other parameters. Much of this information is now publicly available, essentially instantaneously, via the world wide web (interested readers can most easily obtain access through the web site of their particular nation's weather service).

Examination of the climates of the three other large solid bodies in our solar system with substantial atmospheres—Venus, Mars and Titan—reveals very different climate regimes. Venus exhibits a massive CO_2 atmosphere that stands as a stunning example of the effect of greenhouse warming. Mars' thin atmosphere of CO_2 is driven by a combination of processes familiar to terrestrial climatologists but with significant differences in the seasonal cycling of CO_2 into and out of the Martian polar regions, and the occurrence of occasional global dust storms. In addition to the deep atmospheres of the outer planets, the thick atmosphere of Saturn's moon Titan supports a modest greenhouse and a temperature profile with a shape very similar to the Earth's, although hundreds of degrees Celsius colder. By studying the climates of these other solid worlds it is possible to gain some insight into the conditions required in other planetary systems for habitable planets to exist (see also MARS: ATMOSPHERE, VENUS: ATMOSPHERE, TITAN).

Humanity is changing the chemistry and energy balance of the Earth's atmosphere by introducing large amounts of carbon dioxide, chlorofluorocarbons (CFCs) and other products of our industrial–agricultural civilization into the air and water. The CFCs reduce the thickness of the Earth's high-altitude ozone layer, which protects exposed organisms from lethal ultraviolet energy from the Sun. Carbon dioxide and other gases enhance the infrared blanketing effect in the atmosphere, hence warming the planet as well as changing the behavior of the climate system on a timescale of decades. Informed decisions regarding controls on emission of greenhouse and ozone-destroying gases require a deep understanding of how the climate system works, an understanding that is being gleaned from new generations of surface, airborne and spaceborne instrumentation (see also GREENHOUSE EFFECT, OZONE HOLE).

Components of the Earth's climate system

Atmosphere

The atmosphere is what we most associated with climate, and it plays host to the short-term and spatially localized variability termed weather. Earth's atmosphere is mostly molecular nitrogen (N_2), constituting 78% of the air

Copyright © Nature Publishing Group 2001

by number. Approximately 21% of the atmosphere is molecular oxygen (O_2), a product of plant and microbial photosynthesis that reacts with common minerals and would disappear in less than 10 million years in the absence of these processes. Water vapor, because it condenses to form clouds, and is connected through condensation and evaporation to the Earth's oceans and land, is highly variable from place to place and with altitude (see WATER CYCLE). On a global average its mixing ratio near the base of the atmosphere is 1%. Carbon dioxide (CO_2) is the primary supply of carbon to the plant and bacterial photosynthetic cycle and currently constitutes 330 parts per million (0.000 33) of the atmosphere. The total mass of Earth's atmosphere is estimated to be 5×10^{18} kg, determined through the atmospheric density–altitude structure.

The atmosphere can actually be thought of as concentric layers of gas each of which is distinguished by particular mechanisms of energy transport and hence temperature profile. The *troposphere* is characterized by falling temperature with altitude (except near the surface, where locally temperature can rise with altitude in a thin *inversion* layer). In the troposphere, convection and radiation carry heat upward from the surface which is warmed by visible solar radiation. It is here that nearly all clouds form and weather occurs, land–sea–air exchange of gases takes place and the biosphere exists. The troposphere ends at the *tropopause*, about 8 km above in the surface in the polar regions and 13 km in the tropics (with substantial seasonal variations as well). Here the temperature profile reverses direction, and temperature begins to increase with altitude in the *stratosphere*. The stratosphere is warmed by absorption of solar ultraviolet and infrared radiation, largely by ozone (O_3) as part of its photochemical cycle of creation and destruction. As ozone declines, cooling by emission of radiation to space by CO_2 leads to a halt in the rising temperature at the *stratopause* roughly 50 km above the surface; above the temperature falls with height in the *mesosphere*. Beyond 100 km altitude photolysis (breaking of a molecule by absorption of photons) of O_2 and ionization increase the temperature steeply with altitude in the *thermosphere*, where conduction replaces radiation as the key energy transport process. In the ensuing discussion of climate only the stratosphere and troposphere are considered, within which lies over 90% of the total atmospheric mass.

The Earth's rotation and differential solar heating as a function of latitude and time of year drive atmospheric circulation patterns. Solar heating is greatest at the equator and least at the poles; hence the atmosphere must transport heat from equator to pole. It does so through the so-called Hadley circulation, in which warm air rises and is transported to higher latitudes, cools and sinks. The Hadley circulation does not consist of a single cell in the case of the Earth; instead three cells in each hemisphere move heat poleward. As seen in figure 1 rising air at the cell boundaries diverges, leading to belts of low-pressure air, whereas sinking air converges at cell boundaries yielding zones of higher pressure. Since the Earth rotates this pattern of high and low belts is accompanied by the prevailing *zonal* wind pattern also shown in figure 1. The *westerlies* increase in speed with altitude, reaching a maximum just below the stratosphere as the narrow *jet streams*, which are responsible for the movement of mid-latitude storm systems. The *trade winds*, blowing from the east, are a primary driver of the oceanic Gulf Stream through frictional stresses on the sea surface.

Superimposed on the primary circulation pattern described above is a series of secondary high- and low-pressure systems associated with perturbations in the basic flow. The Earth's rotation creates an effective *Coriolis* force that acts at right-angles to the direction of the wind: to the right in the northern hemisphere and left in the southern. At latitudes higher than 10°, and altitudes above the frictional boundary layer of the atmosphere, the Coriolis force is sufficiently strong that it nearly fully balances the pressure gradient force between high- and low-pressure centers. This *geostrophic* balance causes areas of high pressure to spin in a clockwise direction and low-pressure areas to spin in a counterclockwise direction, in the northern hemisphere—and in the opposite sense in the southern. Low-pressure areas are thus *cyclonic* (in the northern hemisphere) regions where rising air forms clouds and precipitation systems if enough moisture is available. Anticyclonic high-pressure areas are characterized by subsidence, evaporation and hence drying; they are generally fair-weather features (again the direction of circulation is reversed in the southern hemisphere). Some high- and low-pressure systems are persistent features, either seasonally or annually, but may fluctuate in strength and position from year to year. Others are spatially and temporally variable, such as mid-latitude storm systems and hurricanes.

Mid-latitude and tropical cyclonic systems exist because of perturbations in the flow that grow with time. *Baroclinic instabilities* are triggered by the existence of a meridional (north–south) temperature gradient in a geostrophic atmosphere and hence are responsible for storm systems at mid-latitudes (where the Coriolis effect is strong). *Barotropic instabilities*, on the other hand, operate at equatorial latitudes, and are a class of instability in which only kinetic (not thermal) energy is transferred from the background rotation of the atmosphere to the growing perturbation. Barotropic instabilities are thought to produce tropical depressions, which in some cases become tropical storms or hurricanes, in the equatorial belt of low pressure called the *intertropical convergence zone* (ITCZ).

In contrast to the geostrophic balance of the terrestrial and Martian atmospheres, on Venus and Saturn's moon Titan stratospheric winds are more rapid than the planetary rotation. The resulting strong centrifugal force dominates over the Coriolis force, leading to so-called *cyclostrophic* balance.

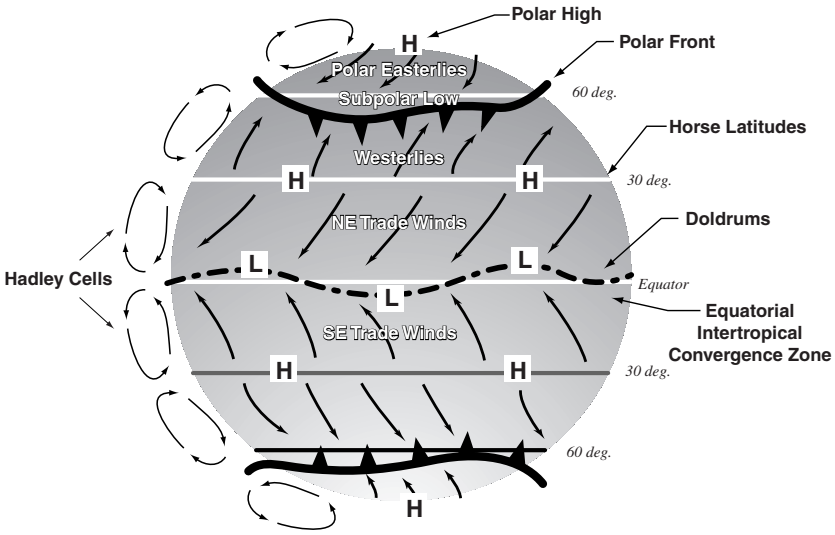

Figure 1. Persistent features of the Earth's atmospheric circulation. Shown is the pattern of permanent high- and low-pressure belts and the Hadley cells that move heat from equator to pole in each hemisphere. The doldrums are the equatorial regime of very calm air; horse latitudes refer to the narrow belts of high pressure over the oceans at about 30–35° latitude. Labeled also is the pattern of atmospheric winds corresponding to the pressure belts; the mid-latitude and higher winds in the southern hemisphere mirror those in the north and are not indicated.

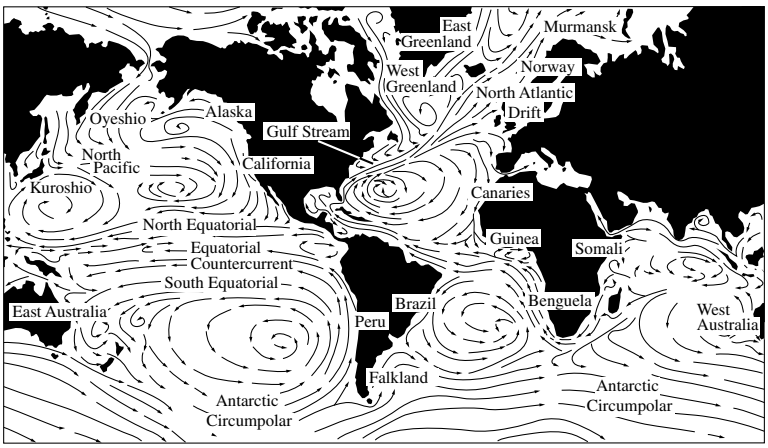

Figure 2. Ocean circulation patterns. Primary surface currents during wintertime are shown, after Peixoto and Oort (1992).

Hydrosphere

The Earth is unique among the solar system's planets in having a massive layer of liquid water, our ocean. In addition to oceanic water, fresh water systems are distributed over the Earth's surface in the form of rivers and lakes. There is also a substantial amount of water circulating through the upper crustal layer of the Earth's interior. This water mixes with the deep ocean on a wide range of timescales, from very short to geological (i.e. millions of years). The liquid water system as a whole is referred to as the *hydrosphere*, and has a mass estimated at 1.7×10^{21} kg, the vast majority of which is in the ocean. Thus the amount of water in contact with the atmosphere on timescales much shorter than geological amounts to 200 times the mass of the Earth's atmosphere, and strongly modifies the response of the climate to changes in external conditions, as well as creating forcing functions of its own. The oceans effectively store large amounts of thermal energy (originally sunlight) that is later released as sensible or latent heat. The temperature of the ocean has a direct effect on the amount of water vapor, the principal greenhouse gas, released into the atmosphere; the oceans also store large amounts of CO_2 (the other primary greenhouse gas) in a temperature-dependent fashion. The average depth of the ocean is 4 km; some of the deepest portions mix with the upper layers or the atmosphere only occasionally, while the uppermost part of the ocean exchanges gases and heat with

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the atmosphere very rapidly and continuously. The ocean moves heat from equator to pole in amounts comparable with what is transported by the atmosphere.

In contrast to the atmosphere there is a large-scale day-to-day uniformity of temperature near the surface of the ocean and a slow seasonal shift. Like a large indoor swimming pool the ocean damps out temperature variations in the atmosphere and controls the lower atmospheric humidity (water vapor content) over large areas of the Earth. The ocean exhibits circulation patterns that bring warm currents of water to high latitudes and cold water to equatorial regions (figure 2). These reduce the north–south gradient of temperature in the atmosphere. The Atlantic Gulf Stream is the best known example of the former. The southward Pacific current off the California coast is a familiar example of the latter, making summer ocean water very cold as far south as Los Angeles. Surface currents are driven by wind stresses, and convergence or divergence of flows leads to vertical motions (downwelling or upwelling) below the surface. This is not, however, the whole story. The oceans contain about 3 parts per thousand dissolved salts, which both lower the freezing temperature of the water and change its density. The former effect allows annual mean temperatures at high latitudes to be nearly 2 °C below freezing. The density effect is such as to make waters of increasing salinity denser.

The deep circulation patterns in the ocean are poorly known, because of a dearth of observations. Thermal and saline (*thermohaline*) density effects, compressibility of the ocean water (actually quite important at large depths) and mass conservation associated with return flow of water from surface currents drive overall ocean circulation. Because of compressibility and thermal effects, very cold, deep, ocean water may not exchange with the near surface more frequently than hundreds of years. The positions of the continents play a key role in the circulation, and in particular may affect the efficiency of north–south heat transport. The role of wind in driving ocean currents and the effect of currents in redistributing heat available to the atmosphere results in a complex, coupled ocean–atmosphere climate system.

The premier example (and possibly the most important in determining global climate state; see below) is the Gulf Stream to North Pacific conveyor belt. The Gulf Stream current is powered by the stress of trade winds exerted on the ocean surface in the tropics, and of the westerlies at mid-latitudes. The current moves warm waters northeastward, along the United States east coast. Evaporation increases the current's salinity; exchange of heat with the atmosphere along the route leads to a net cooling of the water and warming of the atmosphere. The resulting progressive, northward densification reaches a critical stage near Iceland, where the Gulf water becomes denser than the surroundings and sinks. The overturn is aided by winds which blow colder surface waters aside, allowing deeper parts of the current to rise, release heat, and cool rapidly. The now-bottom water flows southward, around Africa and then northward to the colder North Pacific. There it rises to the surface and the divergence pushes ambient waters aside, some moving southward toward the start of the Gulf Stream. The most important consequence of this circulation is to transport significant amount of equatorial heat to the North Atlantic region, strongly moderating the climate of Europe and hence preventing the buildup of massive ice sheets.

Cryosphere

The cryosphere comprises the Earth's permanent and seasonal ice sheets and snow, as well as permafrost, which together account for 80% of the planet's fresh water supply. The major components are the ice sheets of Antarctica, Greenland, permafrost in North America and Asia, sea ice, mountain glacier systems and seasonal snowfields. Although only about 2% of the Earth's water is frozen, the cryosphere has a profound effect on present-day climate and on the glacial–interglacial oscillations of the past 2 million years. The very high reflectivity of water ice (which is sensitive to particle size and hence formation conditions and age, as well as to impurities) rejects by reflection solar radiation in the visible and near-UV parts of the spectrum. In the thermal infrared, water ice is quite dark, and hence acts as a very efficient nighttime radiator of terrestrial thermal radiation. The large latent heat of melting of water ice also acts as a strong heat sink, particularly during colder epochs in which more massive glaciation exists than at present.

The cryosphere amplifies the effect on climate of the northern–southern hemisphere dichotomy in distribution of continents and oceans. Because the northern hemisphere has far more land area than does the southern, development of massive continental glaciation to mid-latitudes, a feature of glacial epochs, is predominantly a northern hemisphere effect. This in turn may tie the timing of onset of glaciations to configurations of the Earth's orbital and spin parameters that produce minima in annually averaged northern hemisphere insolation. On much shorter (seasonal) timescales, however, the presence of a large polar continent in the south and polar ocean in the north affects the relative responses of the poles to the decreased wintertime insolation.

Greenhouse warming

The suitability of Earth for life is in large measure a result of the stability of liquid water at the surface; the annually averaged global mean ocean surface temperature is 288 K. Yet simply equating the annually averaged amount of solar radiation absorbed by Earth's surface to the outgoing bolometric thermal radiation produces an effective temperature of 255 K, well below the freezing point of water (even with salts). The high surface temperature of the Earth, and hence the stability of liquid water, is a consequence of the higher mean opacity of the atmosphere in infrared (where thermal radiation is released toward space) than in optical wavelengths (where the peak of the solar spectrum occurs). The term

greenhouse effect is indelibly affixed to this basic property of the terrestrial atmosphere, despite that fact that in a greenhouse thermally driven convection plays essentially no role at all, while it is important in regulating the lower temperature of the Earth's atmosphere.

The wavelength distribution of photons streaming from the Sun, approximated as a blackbody at 6000 K, peaks at about 0.6 μm wavelength (see BLACK-BODY RADIATION), where atmospheric gases have almost no absorption (with the exception of the so-called ozone *Chappuis* bands). Thus in a cloudless atmosphere sunlight would be virtually free to reach the surface (although Rayleigh scattering by molecules of the air preferentially diffuses shorter wavelengths out of the solar beam, leading to the familiar blue sky). Clouds reflect about 20% of the incoming sunlight, while the surface reflects less than 10% on average. About 2/3 of the sunlight incident on Earth is absorbed by the ground or lower atmosphere and converted to photons with a spectral distribution that, if approximated by a blackbody, corresponds to a temperature of 255 K (absent the greenhouse effect; 288 K with the greenhouse warming). The peak of the spectral distribution of these thermalized photons is in the mid-infrared part of the spectrum, at about 15–20 μm wavelength, and the atmosphere is very opaque there. Absorption bands of water vapor and CO_2 dominate, with holes in the absorption spectrum filled in by CH_4, O_2, O_3, nitrous oxides and even man-made CFC's.

At ground level the atmosphere is highly opaque beyond 5 μm wavelength, but the absorptions decrease with altitude as atmosphere column abundance (from a given level to space) and pressure decline. By 10 km the atmosphere is largely transparent again. Thermal photons streaming upward from the ground have mean free paths much shorter than the inbound solar radiation whose energy flux they must balance. Absorption and reradiation of the thermal photons redirect a portion of the flux back downward; the downward-directed flux decreases with altitude as the atmospheric transparency increases. As a result of this inefficiency in outward thermal transport relative to inbound solar visible radiation, the surface temperature must rise above the effective temperature to ensure a balance between ingoing and outgoing energy flux. Altitudes above the surface also must experience elevated temperatures, but progressively less so as one moves outward. Thus the temperature increases between the altitude at which infrared photons are free to stream outward, the *mean radiating level*, and the surface.

The steepness of the temperature increase is modified from the greenhouse value by a number of other energy transport processes. Most important is convection. When the temperature gradient steepens to exceed the idealized, adiabatic lapse rate, the air becomes unstable and bulk vertical motions (convection) transport the heat upward at the adiabatic lapse rate. In the absence of water the relevant adiabatic lapse rate is the so-called *dry* value of 10 K km^{-1}. Water condensation during cloud formation releases latent heat which allows for *moist* (sometimes, *wet*) convective transport of heat at temperature gradients well below the dry adiabat. To a first approximation the observed mean temperature gradient in the Earth's atmosphere is the moist adiabatic lapse rate. Further modification of the temperature profile occurs as winds advectively transport heat from one location to another, and storm systems move both moisture and heat in horizontal and vertical directions. Figure 3 summarizes the various mechanisms for upward and downward energy transport.

The essential point about the greenhouse effect should not be obscured by the complexity of multiple transport processes. Inbound energy flux must be balanced by outgoing, and if the atmosphere is less transparent to outgoing (thermal) radiation than to incoming (solar) radiation, the surface temperature is elevated until the balance is achieved. However, the response of the Earth's climate to the increase in greenhouse gases is difficult to predict because of the large number of degrees of freedom. Modifications to cloud formation, precipitation, surface ice coverage, ocean circulation, temperature and CO_2 solubility all represent responses to increased greenhouse gases that can provide positive or negative feedbacks. The effect of an incremental increase in greenhouse gases can be predicted (incrementally higher surface temperature), but discrete changes (particularly large ones) can simply push the Earth's climate into a different state.

An extreme example of the greenhouse effect is available for study on Venus, where the surface pressure is 92 bar and the atmosphere is 96% carbon dioxide. Because a layer of reflective sulfuric acid and water clouds covers the globe, the surface of Venus receives only a few per cent of the sunlight incident on the top of the atmosphere—less than the Earth receives at its surface despite the latter being 40% more distant from the Sun. Yet the surface temperature of Venus is 730 K, a value that reflects the extreme infrared blanketing afforded by the high CO_2 surface pressure, as well as contributions from minor species such as water vapor (roughly 100 parts per million of the atmosphere). As with the Earth outward energy transport is largely by convection, but on Venus it is entirely dry convection.

Mars' thin atmosphere has a mean surface pressure of only 7.5 mbar and is almost devoid of water. Therefore even though it is 95% carbon dioxide (which yields a CO_2 partial pressure larger than on Earth), absorption bands of carbon dioxide are very narrow in frequency, lacking the broadening afforded by a high pressure of nitrogen; in addition water absorption bands are almost nonexistent. Thus there is only a very small greenhouse effect of 5 K. Solar heating of the surface drives convection and hence produces a troposphere extending to 40 km. However, the lapse rate is much less than dry adiabatic because of a suspension of dust particles in the atmosphere, which absorb sunlight at all altitudes through the troposphere. In some years global dust storms load the atmosphere with so much dust that the ambient atmospheric temperature profile is strongly perturbed.

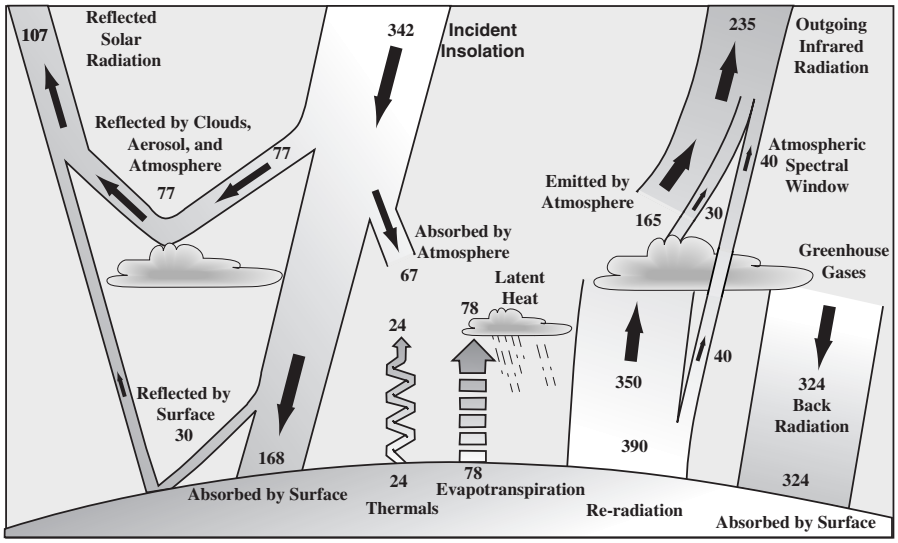

Figure 3. Contributions to sources and sinks of energy in the Earth's atmosphere. Left half of the figure is fate of sunlight (mostly optical), right half the history of reradiated thermal energy, and non-radiative processes are sketched in the center. Energy fluxes in watts per square meter. Redrawn from Trenberth *et al* (1996).

General circulation models: ocean and atmosphere

The fundamental theoretical tool both for weather forecasting and for climate change studies is the numerical *general circulation model*, or GCM. The Earth is divided into a grid with cell sizes as small as practical for the available computational resources. In each grid the following equations are applied: (a) horizontal equations of motion; (b) hydrostatic law; (c) continuity equations; (d) energy balance (first law of thermodynamics); (e) equation of state for moist and dry air; (f) balance equation for water vapor. These form a closed system with boundary conditions specified by meteorological measurements or (for paleoclimate models) geological data and assumptions. With high-speed computers atmospheric motions can be coupled to those of the oceans, leading to ocean–atmosphere GCMs. For the ocean component similar equations to (a)–(f) apply, except that (e) is replaced by the equation of state for ocean water and (f) is replaced by a balance equation for salinity. Over vegetated areas vapor and energy transfer from and to plants by evapotranspiration must also be included. Equations are integrated to track the time evolution, in three dimensions, of atmospheric circulation, intensity and position of high- and low-pressure centers, temperature, heat and mass transfer between atmosphere and ocean, and other parameters.

Because of the vast difference in timescales between atmosphere and ocean some simplification of the ocean model (for example a shallow ocean representing the uppermost well-mixed layer), or averaging of the atmospheric processes, must be made. Increasingly full-up simulations coupling the two are being accomplished as computational power increases. However, significant limitations remain. In the atmospheric case, processes occurring on scales below the grid size can have significant effect. For example, orographic lifting of air masses by localized or topographically complex mountains, small-scale variations in land use patterns or intricate geographical relationships between dry land and bays or seas often cannot be handled well by GCMs. The formation of precipitation is highly sensitive to subscale processes, and hence GCMs are less successful at tracking this process in detail. As we shall see below, variations in precipitation patterns over land and sea may have served as the trigger for profound flips in climate state, and it possible that GCM simulations, particularly if time averaged to track decadal or longer changes, may miss these.

Sufficient observations of the Martian atmosphere have been made to enable application of GCMs of considerable sophistication. The total absence of a global ocean on Mars means that there is no large-scale heat sink to dampen climate variations on seasonal or longer timescales and no source of water vapor to modify atmospheric lapse rates and serve as a source of massive cloud formations. Instead the Martian climate is driven mostly by seasonal cycles of CO_2 and dust. The polar regions become so cold during the winter (150 K) that the primary atmospheric constituent, CO_2, condenses out to form an extended cap in the winter hemisphere. The annual cycling of CO_2 from one winter hemisphere to the other modulates the bulk atmospheric pressure by 30%. This phenomenon, with no analogue on the Earth or Venus, has been measured directly by the VIKING and MARS PATHFINDER landers. Among other effects, it drives substantial variation in the nature of the equatorial to mid-latitude Hadley circulation, which comprises one Hadley

cell at the solstices and two at the equinoxes. At higher latitudes in winter and spring, traveling disturbances exist that are akin to terrestrial storm systems; these are absent in summer. Such systems are detected both by lander meteorological stations and by very tenuous traces of water clouds seen in global imagery.

Climate events: ENSO and the Asiatic monsoon

The El Niño–Southern Oscillation is a climatic phenomenon whose existence and worldwide connections have been recognized only in the past few decades. It provides an excellent example of atmosphere–ocean interactions and the ability of regional ocean-driven perturbations to cause worldwide changes in weather patterns. On intervals of roughly 2–10 yr an unusually strong ocean current pushes warm, low-salinity surface waters against the west coast of South America, where it then moves southward. This phenomenon is referred to as *El Niño*, a co-option of a traditional term used by Peruvian fisherman to describe the annual warming of offshore waters right after Christmas.

Accompanying the warming of eastern Pacific waters is an associated rise of air temperatures. Strong El Niños may persist for more than a year, and perturbations to Pacific ocean currents are generated over many thousands of miles to the west of South America. The atmospheric disturbance accompanying the oceanic changes is even more widespread. During El Niño years, drought conditions occur in Australia, Indonesia, southeastern Africa and northeastern South America, while unusually heavy rains may occur in Ecuador, northern Peru, eastern equatorial Africa and areas south of India. The alteration in weather patterns had traditionally been considered a separate phenomenon involving shifts in positions of seasonal high- and low-pressure patterns, known as the *Southern Oscillation*. It was not until the 1960s that the causal link between it and El Niño was established.

The mechanics of the oceanic perturbation involve waves generated in the Pacific which push warm water toward the east, raising sea level there slightly and depleting the amount of warm water in the western Pacific. The onset and dissipation of this event involve a complex, poorly understood series of interactions between the changed sea surface temperature distribution and the atmospheric temperature pattern. What is not understood at all is the origin of the ENSO phenomenon in its entirety. Proposals range from the idea that the ocean circulation pattern itself drives the oscillation, all the way to the unlikely notion that undersea eruptions contribute heat to the deep ocean and stimulate the effect. Also poorly understood is whether ocean–atmosphere oscillations other than in the equatorial Pacific might exist. Finally, the speculation has been made that ENSO is symptomatic of an increasingly warm climate on the edge of instability, and that cooler times during the Holocene did not experience such oscillations.

The substantial summer rains in the Indian subcontinent and surrounding parts of Asia are a part of the seasonal shift of wind pattern called the Asian monsoon. The great mass of the Tibetan plateau, the large land area of the Asian continent with its concomitant extreme seasonal temperature contrasts and the location of the ITCZ all play a role in defining the monsoon climate regime. Most dramatic is the seasonal shift in winds in the spring, during which mid-level winds change from westerly to easterly, and extremely hot and dry conditions in late spring give way to moist onshore flow as summer commences. A complex continental airflow is initiated leading to large amounts of rainfall in places such as India. The amount of rain delivered both locally and over the whole region varies dramatically from one year to the next and appears to be correlated with the strength of El Niño. Since India and some other Asian nations depend on the monsoon for significant parts of their agricultural water supply, the predictability of monsoon variability and its connection to worldwide phenomena such as ENSO represent climate issues of great human importance.

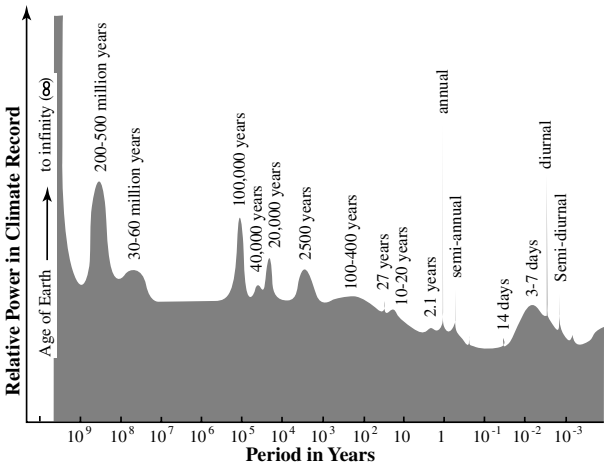

Figure 4. Temporal climate scales. Variance as a function of timescale in climate based on direct observations and proxy indicators from the climate record. After Peixoto and Oort (1992).

Climate change in the past

Information on climate variations comes, on the longest timescales (billions to hundreds of millions of years), from oxygen isotopes in cherts, and geologic evidence including geographical distribution of fossil species and signatures of glaciation. On intermediate timescales (millions to tens of millions of years), isotopic abundances in seafloor sediments (carbon and hydrogen) provide a more detailed climate record. Finally, on shorter timescales a variety of climate proxies are available, from isotopic data in seafloor sediments throughout the Pleistocene, to ice core data (isotopic temperature proxies, carbon dioxide content, etc) and on to tree-ring cores, streamflow data and historical records for the current Holocene stage.

Figure 4 is a power spectrum of atmospheric temperature variations on timescales ranging from geologic to diurnal. The origin of the various peaks, from

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the longest to shortest timescales, is as follows. Isotopic data suggest an overall decline in surface temperature from the time of the earliest sediments, possibly due to declining levels of CO_2 in the Earth's atmosphere. The abundance of this gas is thought to be regulated by complicated interactions between weathering of silicates (leading to trapping of CO_2 as carbonates on the seafloor) and volcanic extrusion of CO_2 associated largely with plate tectonic recycling of oceanic crust and sediments. Geomorphological and isotopic data hint at one and maybe two periods of deep, nearly global ice ages prior to 500 million years ago, as well as (with fossil data) climate variation on hundred million year timescales. Such variations probably reflect the changing positions of the continents, which affect oceanic circulation and hence transport of heat, along with associated changes in seafloor spreading rates, volcanism and mountain building activity, all of which affect the atmospheric CO_2 abundance. The weak variation seen on 10 million year timespans might be volcanically or tectonically driven, but could reflect as well stochastic effects such as oscillations in solar luminosity, and even passage of the solar system in and out of galactic molecular clouds.

The strong signals of climate variation on 10 000–100 000 yr timescales are almost certainly a result of variations in the Earth's axial tilt, orbital eccentricity and phasing of various orbital parameters. These *Milankovich cycles* are a natural consequence of the gravitational effect of the Moon and other planets on Earth, and lead to complex cyclical modulations of the seasonal and annually averaged absorption of solar radiation by the Earth. The variance is strong because the modulations led to oscillations of the Earth, over the last 2 million years, between states of significant northern hemisphere glaciation with duration of order 100 000 yr and warm interglacial periods typically 1/10 the glacial duration. The weak signature of climate fluctuations on the thousand-year scale is related to the mid-Holocene *climate optimum* and subsequent cooling. On historical timescales, the peculiar Little Ice Age which began several centuries ago and ended in the 19th century can be seen as a strong variance, as well as ENSO-type oscillations on decadal and semi-annual scales. Earth's orbital motion, axial tilt and spin (in their current relative orientations) provide strong fluctuations on annual, seasonal and diurnal timescales.

Two particular well-studied examples of climate conditions in the past have relevance to our understanding of human-induced climate change. Isotopic data and geological evidence in the form of fossil distributions and geomorphology argue that the Earth during the time of the Cretaceous (65–100 million years ago) was free of permanent ice sheets. To explain the data the equator-to-pole temperature difference must have been 1/2–1/4 what it is at present, with an equator not much warmer than at present but poles 20–40 °C warmer. Simply doubling or quadrupling the atmospheric CO_2 level does not explain Cretaceous climate, because it raises equatorial temperatures too much. Instead, enhanced oceanic transport of heat from equator to pole is invoked in GCMs that fit the geologic and isotopic data. The origin of such enhanced oceanic heat transport is not well understood; possibly the difference in continental configuration during the Cretaceous could have played a role.

The Younger Dryas episode some 11 000 yr ago, during the transition from cold glacial to warmer Holocene conditions, is especially noteworthy. It was a cold snap in continental areas around the North Atlantic that lasted no more than a century, during which glaciers reversed their retreat. The origin of the Younger Dryas episode paradoxically lay in the melting of the glaciers themselves. Glacial meltwater accumulated in parts of eastern Canada and flowed down the Mississippi with volume rivaling the present Amazon river. Glaciers blocking this massive flow of freshwater from entering the North Atlantic retreated sufficiently by about 11 000 yr ago that the meltwater began flowing eastward. The supposition is that this influx of freshwater to the North Atlantic diluted the saline Gulf Stream sufficiently to prevent its sinking near Iceland, and hence reduced or shut off the associated release of heat. The Gulf circulation stopped, replaced by a stable upper layer of very cold water that chilled Northern Europe and Canada and reinitiated the buildup of glaciers through expanded annual snowfalls and reduced snowmelt. As the freshwater flow subsided the Gulf current returned and warming began again. Very recent ice core data reveal many other rapid episodes of climate fluctuation in glacial and interglacial epochs of the Pleistocene, some on the scale of decades or less.

The above interpretation of the Younger Dryas episode has led to speculation that a similar reversal triggered in the North Atlantic could be in store if human activities accelerate global warming (see below). GCMs predict enhanced rainfall at high latitudes as CO_2 levels increase in the coming century. Sufficient rainfall could decrease the salinity of North Atlantic waters to such an extent that the subsidence of water off Iceland is interrupted as in the Younger Dryas. The resulting shift in climate is hard to predict using GCMs, but conceivably could be in the direction of increased glaciation with positive feedback afforded by the high reflectivity of water ice. The specifics of this putative response to global warming is less important than the general lesson of the Younger Dryas that perturbations associated with climate change in one direction can cause the climate system to flip into a mode that evolves in a quite different direction.

Human induced global warming

Beginning in the mid-19th century CO_2 levels in the atmosphere began to increase as a result of human activities, including burning of fossil fuels and deforestation. The present CO_2 abundance is 30% higher than the base level before the increase. In addition, human activities are enhancing the abundances of CH_4 and CFCs in the atmosphere which add to the infrared absorption along with CO_2. Increasing the greenhouse gas content of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the atmosphere forces the mean radiating level to move upward; in response the mean surface temperature must increase to balance incoming solar flux. However, the complexity of the various effects associated with such a change, including cloud and precipitation shifts as well as the role of the ocean in storing and releasing heat and carbon dioxide require use of a GCM to predict in detail the resulting climate changes.

Direct temperature records over the past hundred years as well as proxy temperature indicators available throughout the Holocene suggest that the last decade was exceedingly warm, perhaps the warmest of the past 1000 yr. Much political debate surrounds the interpretation of the data (natural fluctuation or human-induced global warming?) and the utility of GCMs in predicting local or regional impacts. The climate may respond linearly to increasing greenhouse gas content, at least for a while. However, the Younger Dryas and other evidence of rapid climate shifts in the geologic record serve as a warning that human activities, in perturbing the composition of the atmosphere, will force us to deal with substantial and probably undesirable rapid shifts in climate.

The future of climate studies

The future of climate studies will depend, as over the last half-century, on cooperative international programs of monitoring climate and evaluating climate data. Special programs, often time limited and sometimes motivated by political as well as scientific imperatives, benefit the field of climate studies through additional funding and attracting talented students to the field. The International Polar Years in 1882–3 and 1932–3 were early examples focused on data collection in the arctic. The International Geophysical Year from 1957 to 1958 demonstrated the feasibility of much broader-scale, if not global, coordination of data collection on a range of Earth studies including climate. More recently the World Meteorological Organization and the United Nations Environmental Program established the International Panel on Climate Change, which has produced several major published assessments of the state and near-term future of the Earth's climate.

Spacefaring nations coordinate satellite observations and, in the case of the United States and Europe, are in the process of implementing major space-based systems to monitor Earth's climate with a level of accuracy and breadth of coverage far exceeding previous efforts. These satellite systems represent current investments of billions of dollars and euros and will grow in the future. Impressive increases in computational capability will benefit study of climate in two ways, allowing more elaborate and higher-fidelity climate models and enabling collection and processing of very large data sets on Earth's climate. New computational approaches to processing the information and the availability of the world wide web make climate data more understandable and accessible to researchers and policymakers alike. The gradual accumulation of spacecraft data on Mars, Venus and Titan has permitted GCMs to be applied to these other three solid planetary bodies with substantial atmospheres. Such efforts test our understanding of the physics of climate in regimes very different from that of Earth itself. As our experience with the Earth's climate grows in detail alongside the exploration of other planetary climates our understanding of the processes involved will deepen dramatically.

Close Binary Stars

Often a star is found to have a companion star which is very close to it. Often also the two stars would fit comfortably inside our solar system, whose radius is about a ten-thousandth of the distance to the next nearest star. Sometimes the two stars are so close together as to be virtually touching. In a few cases they are genuinely touching, and even overlapping, so that we may have a single figure-of-eight-shaped entity (a 'contact' binary) consisting of two stellar cores within a single thin envelope.

Most close binaries (CBs) are discovered by one of two techniques: (i) they may show a periodic Doppler shift due to motion in a Keplerian orbit (SPECTROSCOPIC BINARY STARS, or SBs) or (ii) they may show periodic eclipses as one star passes in front of the other (ECLIPSING BINARIES, or EBs). SBs and EBs have periods ranging from ∼30 yr down to a few days, and even a few minutes. Specifically, we set a period of 30 yr as an upper limit for 'close'. This implies separations, by Kepler's third law, of less than the orbit of Saturn, approximately.

There are other ways of recognizing some classes of CB. For instance, eruptions of the NOVA and dwarf nova category are indicative of binarity, and so (often, but not always) is the production of x-rays. However, the binarity of such objects is only known because a very high proportion of them are found on close inspection to be either SBs or EBs (or both). The statistical distribution of periods in CBs is not yet well determined. Although several thousand SBs and EBs are known, their detection is subject to many selection effects. For example, short periods are usually easier to recognize than long periods. The most systematic studies tend to show that longer periods, say 3–30 yr, are more common than short, say 3–30 days, but only by a modest factor, perhaps a factor of 5. Among stars similar to the Sun, probably about 20% are CBs as defined above, while among massive stars of spectral type O the proportion must be much higher because about 25% have periods of up to only about 30 days. Longer-period spectroscopic orbits among O-type stars are hard to recognize, because such hot and massive stars tend to have an intrinsic spectral 'jitter' which can conceal the orbital motion.

If two solar-type stars are in orbit about each other (strictly, about their center of gravity) with a period of about 10 yr, they would be about as far apart as Jupiter from the Sun. We might not think of this as close, because their separation would be almost a thousand times as large as their radii. However, as stars evolve they become larger, ultimately by a factor of several hundred in radius and perhaps even a thousand (see STELLAR EVOLUTION). Clearly when one star is almost as large as the orbit in which it finds itself, something rather drastic must happen. There is much observational evidence for this, some direct and some indirect. Directly, we observe a number of binaries in which a stream of gas is flowing from one star to the other. Indirectly, we see a number of CBs containing compact stellar remnants: WHITE DWARFS (WDs), NEUTRON STARS (NSs) and even BLACK HOLES (BHs). These remnants may appear fairly far apart in their present binaries but must be descendants of stars which were once much larger. They may be in binaries that are too close at present ever to have contained normal stars, so that some interaction must have taken place in the past.

CBs are of interest for at least three very different reasons. Firstly, careful measurement of the orbit, especially in systems which are both SB and EB, can lead to determination of the masses and radii of stars. This is in fact the only reliable way of determining such fundamental parameters. Secondly, they show a wide range of physical processes that are not to be seen in single stars, for instance gas streams that may be torn off one component and accreted by the other. Thirdly, they allow us the opportunity to test conclusions about the evolution of stars. This article will concentrate mainly on the third aspect.

A star of given initial mass begins the major part of its life at a modest radius, comparable with the Sun's, when nuclear fusion (the burning of hydrogen to helium) becomes established in its central core. It is a 'main sequence' (MS) star, and remains so, expanding slowly by a factor of about 2.5 in radius until it has exhausted the hydrogen fuel in its center. Then it evolves more rapidly to a large radius, high luminosity and low surface temperature: it becomes a RED GIANT (RG). The central energy-producing core by contrast becomes more compact. The lifetime as an RG is typically ∼10–30% of the lifetime in the MS band. Finally either (a) it reaches such a high luminosity that it is able to blow off most of its outer layers through a strong stellar wind or (b) in more massive stars the core becomes so compact that gravity causes it to implode, and the sudden release of gravitational energy in the core blows the envelope off in a supernova explosion. The remnant in either case is a compact inert object, a WD in case (a) and an NS or a BH in case (b). The lifetime of this remnant is extremely long, but at the same time the object is very faint and therefore inconspicuous.

It appears to be a rather fundamental property of the evolution of stars that, as they age, their cores become smaller and their envelopes become larger. The present Sun has about 50% of its mass in the inner 50% of its radius. However, the Sun will become an RG in about 5 Gyr, and at a late stage in this process the inner 50% of mass will have shrunk into a core (effectively a WD) of one-twentieth of its present radius while the remaining 50% will have expanded into an envelope about 300 times its present radius. At the same time its luminosity will have increased to several thousand times its present value. More massive stars go through rather similar stages, but more rapidly the greater the mass.

Evidently, such expansion must somehow be modified if the Sun had a binary star companion in, say, an orbit like the Earth's. This orbit has a radius about 200 times that of the Sun. In fact when the Sun has reached a radius of only about 80 times its present value, the presence of this

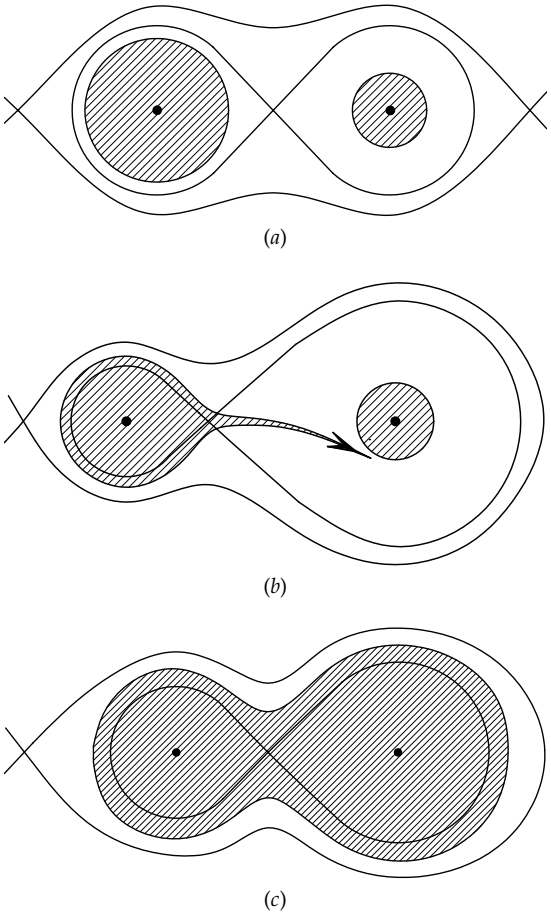

Figure 1. Critical surfaces for two stars in a CB. (*a*) The two stars both underfill their critical surfaces, forming a stable detached (D) pair. (*b*) One star fills its critical surface, to form an unstable semidetached (S) pair. (*c*) Both stars overfill their critical surface by the same amount, to form a stable contact (C) pair.

hypothetical companion in the Earth's orbit would cause the Sun's envelope to become unstable. The critical size is determined by its 'ROCHE LOBE' (figure 1). For any pair of masses, and any orbital separation, there is a critical figure-of-eight-shaped surface which has one component at the centre of each lobe. If the star's volume grows to exceed the volume of its Roche lobe, the star becomes unstable. Its material should pour out of its lobe through the crossover point, and into the other lobe.

Several stars are observed to be doing just this. For instance, in Algol (β Per), the first EB to be discovered (by Goodricke, in 1783), the radius of one component is closely equal to its lobe radius, and the presence of a gas stream in the system has long been recognized by the presence of emission lines. In an apparent paradox, the star which fills its lobe is less massive than the companion, contradicting the theoretical expectation that the more massive star should be the one to become unstable first. The answer to this is that the star which was originally more massive did indeed become unstable first, but then lost so much of its outer layers because of its instability that it is now the less massive by a large margin. Most, but probably not all, of the mass lost was accreted by the companion, increasing the margin even more.

Four aspects of stellar evolution are particularly important in shaping our expectations about binary stars.

(i) Stars tend to increase in size with age, at least as long as the star still has nuclear fuel to burn. They preserve their initial mass for most of their life, but at a late stage of high radius and high luminosity they eject a considerable fraction of their mass into space, leaving a compact, fuel-exhausted remnant.

(ii) The rate of evolution increases strongly with the degree of evolution; an extreme RG is evolving a hundred times or more faster than on the MS.

(iii) The rate of evolution is very sensitive to the initial mass of the star: if one component of a binary is say 20% more massive than the other, it can be expected to run through its entire life and become a compact remnant, while the other remains little changed on the MS. Stars whose initial masses are less than the Sun cannot evolve significantly at all, in the lifetime (believed to be ∼10–15 Gyr) of the universe.

(iv) The nature of the remnant (WD, NS or BH) probably depends mainly on the initial mass of the star, although with a great deal less certainty than the three previous propositions. WDs appear to come from stars no more than 6 or 7 times as massive as the Sun, BHs arguably from stars more than 30–50 times as massive as the Sun and NSs from intermediate masses. There may be some substantial overlap, however, perhaps depending on some apparently minor properties of a star such as its rotation rate, or the strength of its magnetic field.

The preliminary expectation is that, just as the evolution of a single star is mainly dependent on a single quantity, its initial mass, so the evolution of a binary will mainly depend on three quantities, the two initial masses and the orbital period (or equivalently, separation) (see CLOSE BINARY STARS: FORMATION AND EVOLUTION). The last of these will determine how far in its evolution the star of larger initial mass can proceed before it becomes unstable by filling its Roche lobe and transferring mass to its companion. Beyond this point, the evolution of both stars can become markedly different from what it would have been if they were not in the binary.

The three quantities referred to above, two masses and a period, determine (by Newton's law of gravity) not only the separation but also the angular momentum. It is a cardinal principle of physics that in an isolated system angular momentum is conserved. The transfer of mass between the stars, once one fills its Roche lobe, will alter the period and separation of the two stars, but should not (one might suppose) alter its angular momentum. This principle allows us to predict what the future evolution would be after the onset of mass transfer (usually referred to as Roche-lobe overflow). On this basis, we expect roughly the following:

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

(a) the loser continues to lose mass until it is stripped down to its compact (WD) core, the orbit becoming substantially wider in the process;
(b) the gainer, which is probably still an MS star unless its initial mass was rather closely equal to the gainer's, will start to evolve faster, and will in turn become large until it fills its own Roche lobe.

In practice, however, the situation appears more complicated. The likely explanation is that stars, especially in binaries, lose mass, not just to each other but to (in effect) infinity, so that the system is not isolated. The mass lost to infinity can carry angular momentum. If this mass is relatively rich in angular momentum, compared with the original binary, the loss can make the binary smaller. If it is relatively poor, it can make the binary wider, even (somewhat surprisingly) so wide that it becomes unbound, the two components themselves going to infinity in different directions.

Two rather extreme examples may illustrate this. The star 0957 − 66 (see table 1) is a binary of two WDs, both with masses about one-third of solar. The orbital period is less than 1.5 h. Even the total mass is too low for there to have been any evolution, and so the system must have lost at least a third of its original mass; more realistically, at least 60%. Also, the angular momentum is too low, by an even larger factor, for the system to have once contained two MS stars capable of significant evolution. The system must have lost at least 85–90% of its original angular momentum.

At the other extreme, we noted above that a high proportion of massive (O-type) MS stars are in CBs. O-type stars can be expected to evolve into NSs, and yet NSs are observed to be overwhelmingly single; only about 5% of radio pulsars are found in binaries. This suggests that the supernova explosion that accompanied the collapse of the core to NS size removed a good deal of mass, easily more than 50% of the system's original mass, while removing disproportionately little of the angular momentum. Such a process can disrupt the binary entirely, giving one and in the longer term two isolated NSs. A variant of this is that the supernova explosion has a degree of asymmetry to it, so that the remnant of the explosion receives a 'kick' which can be strong enough to eject it from the system.

In understanding the evolution of CBs we must therefore pay attention to possible processes causing mass loss or angular momentum loss, in addition to any Roche-lobe overflow that is to be expected. A few processes are listed here.

(a) Gravitational radiation is bound to cause angular momentum loss, though normally on a very slow timescale. However, the WD pair mentioned above should spiral into each other in less than 1 Gyr.

(b) Magnetic activity can cause mass loss. This activity is believed to be the driving force in the solar wind. Such wind is much stronger in evolved RGs than in MS stars, especially the relatively rapidly rotating RGs that are often found in CBs. The magnetic field, linking the star to the wind, can cause 'magnetic braking', a possibly efficient angular momentum loss process. A 0.1% loss of mass might be accompanied by a 10% loss of angular momentum.

(c) Even single stars lose much mass, perhaps 50–80% of the initial mass, because of much stronger 'superwinds' in their highly luminous latest stages. Some of this may be accreted by the companion even if neither star ever fills its Roche lobe. This mass loss will probably not cause much angular momentum loss, and the final binary might be about as close as the initial binary, or even slightly wider.

(d) Roche-lobe overflow can cause a catastrophic runaway if either the mass ratio (loser/gainer) is large or the loser has a deeply convective envelope such as is expected in an RG. The mass shed by the loser, instead of accumulating on the gainer, may accumulate in a 'common envelope' around the system and ultimately be expelled, carrying not only a large amount of mass but also a disproportionately large amount of angular momentum, so that the final binary may be a great deal smaller than the initial one. This process may even lead to coalescence, the remaining object being a rapidly rotating single star.

(e) As indicated above, a supernova explosion may remove much mass, and either increase or decrease the angular momentum in the remaining mass. A well-aimed 'kick' may even cause coalescence, the NS remnant hitting the MS companion and sinking to its centre.

Many observed binaries appear to have been modified by one or more of these processes, possibly in addition to Roche-lobe overflow.

Table 1 lists a number of binaries and their astrophysical parameters such as period, masses, eccentricity, separation and radii (where known). They demonstrate a wide range of evolutionary states, for each component. As well as the states MS, RG, WD, NS, BH we include two more, pre-main-sequence (PM) and hot remnant, which we describe below. A state such as 'RG + MS; S' means that there is an RG and an MS star in a 'semidetached' (S) state—figure 1(*b*)—where the larger star fills its Roche lobe. D refers to a 'detached' state—figure 1(*a*)—and C to a 'contact' state—figure 1(*c*).

TY CrA is an apparently very young binary, where the less massive star is still shrinking towards the MS; hydrogen fusion has not yet achieved equilibrium. When it does, the system will somewhat resemble GG Lup, where the less massive star is also the smaller. α Vir (Spica), GG Lup, RT And, α Aur (Capella) and V2291 Oph are all normal systems, some very close and some wider, in which no Roche-lobe overflow has yet occurred. In each case the more massive star will fill its Roche lobe in due course. In α Aur we see that both stars are giants: in comformity with point (iii) above they have nearly equal masses. V2291 Oph has quite a long period ($\sim$1 yr). If it were $\gtrsim$20 times longer still, the RG might well evolve without Roche-lobe overflow, but with a final superwind episode—process (c) above—that would turn it into a WD without much effect on either the period or the other star.

Period (P) in days, unless specified; eccentricity (e) is zero unless stated; semimajor axis (a) in solar radii; masses (M) and radii (R) in solar units. A colon indicates substantial uncertainty. Evolutionary 'state' is explained in the text.

This would leave it like α CMa (Sirius), where the WD has only half its companion's mass but was presumably once the more massive component. Further evolution of the second star in V2291 Oph would be similar (still supposing that the period were longer) and leave a wide pair of WDs like EG52.

However, ζ Cap shows that some significant interaction can take place with orbital periods of a few years. Here one star, presumably the more massive originally, is a WD, but the companion RG has a spectrum unusually rich in barium (Ba)—and also some other elements. These elements are expected to be formed by nuclear fusion only at a very late stage in evolution, shortly before the superwind stage. They must have been produced by the first star, ejected in its superwind, and accreted by the second star where it now shows up in the spectrum.

BF Cyg is possibly in a state that ζ Cap will evolve to, when its giant component is even larger. This 'symbiotic' system shows a combination of a cool, very large star and a small hot object, possibly a hot remnant of an RG that has lost its envelope but is not yet a WD. The hot remnant seems to be interacting with a wind from the current RG component, that perhaps half-fills its Roche lobe. When it does fill its Roche lobe, the interaction may be quite dramatic—case (d) above—leading to a common-envelope phase and leaving a WD + WD pair, probably intermediate in period between 0957 − 66 and EG52.

CI Cyg is another symbiotic system, but here the hot object is arguably an MS star, heated by accretion from the RG wind, rather than a WD. It is therefore less rather than more evolved than ζ Cap (and probably of substantially less mass). A common-envelope episode looks rather likely, because the future loser, the RG, is perhaps three times as massive as the gainer. The mass expelled in the common envelope may briefly shine as a planetary nebula in the UV light from the exposed RG core (a hot remnant), and if the period is severely decreased by the common-envelope phase, as expected, we may get an object like UU Sge, which is surrounded by the planetary nebula Abell 63. A number of other planetary nebulae have CB central stars, which are most easily understood as remnants of a common-envelope phase (see BINARY STARS IN PLANETARY NEBULAE).

In UU Sge the hot remnant might be expected to cool off quite soon to a WD, and then the system might not change further because the other star has too little mass to evolve—point (v). However, angular momentum loss by process (b) might well operate, since cool rapidly rotating MS dwarfs are well known to be magnetically active. This would shrink the binary until it might become

Dirac House, Temple Back, Bristol, BS1 6BE, UK

like DQ Her, where the cool dwarf fills its Roche lobe. Such binaries are 'cataclysmic' variables, which show episodic outbursts. These are due to a combination of instability in the accreting gas flow (dwarf novae) and thermonuclear instability in the gas recently accreted on the surface of the WD component (classical novae) (see CATACLYSMIC BINARIES: CLASSICAL AND RECURRENT NOVAE). DQ Her had a classical nova outburst in 1934.

Systems of short period initially, such as GG Lup, α Vir and RT And, should reach Roche-lobe overflow much sooner than say CI Cyg, perhaps even before making the transition from MS to RG. λ Tau and β Per (Algol) are two such binaries with ongoing Roche-lobe overflow. The first may be descended from a relatively massive system, intermediate between α Vir and GG Lup, the second from something intermediate between RT And and GG Lup. The loser in β Per is now an RG, but was probably MS when Roche-lobe overflow began. Unlike in the wider systems such as V2291 Oph or CI Cyg, there is no room for the RG, in the future, to evolve to large radius and a massive WD core. Instead the RG in β Per is likely to lose all its envelope when the core is still a low-mass object. The product will be a system like V1379 Aql, where the hot remnant (not yet a WD) is only 10% of its companion's mass, and is presumably the remnant of a former RG. The companion in V1379 Aql has itself evolved from the MS to become an RG, and soon will fill its own Roche lobe. The severe mass ratio will probably make this a common-envelope event—point (d)—and the next stage will be two low-mass WDs, in a very short-period orbit, presumably like $0957-66$. Gravitational radiation—point (a)—will cause these WDs to spiral in towards each other, on quite a short timescale (about 10 million years), to give a third episode of Roche-lobe overflow. The system may resemble AM CVn, which appears (but with considerable uncertainty) to be an ultrashort-period binary of two WDs with the larger (and less massive) component overflowing its Roche lobe.

Some binaries, such as Z Her, are wide enough for one component to become at least a small RG before Roche-lobe overflow. It is odd here that the more evolved component is slightly less massive than its companion. This may be because of point (b) above; magnetic activity may cause much faster than normal mass loss by stellar wind, shortly before Roche-lobe overflow begins. However, the companion is itself quite evolved, and may also be an RG when Roche-lobe overflow begins. We may therefore get a double-RG semidetached binary, like RT Lac. The later evolution may also take the system through stages like V1379 Aql, $0957-66$ and AM CVn.

In a system initially like RT And, where the two components are almost touching even though they are hardly evolved, we can expect that very shortly after Roche-lobe overflow the components actually come into contact (figure 1(c)). Both nuclear evolution and magnetic braking—point (b)—may work to make the system even smaller during this contact phase, but can do so only if the mass flow is on average reversed, so that the less massive star is gradually absorbed into the more massive. This may be the origin of a system like ϵ CrA, which must be at quite an advanced stage since one component is 10 times as massive as the other. An oddity in this and other contact binaries is that the two components are at roughly the same temperature and luminosity, whereas if they were separate the less massive component would be at least 1000 times fainter. This seems to indicate that when two stars are in contact the hotter one heats up the cooler one by sending energy through the narrow 'neck' joining them (figure 1(c)). Presumably mass flows slowly in the opposite direction, until the less massive star is entirely swallowed up, and what remains is a single star giving little indication of its former binary history.

If one component is massive enough, it may be destined to end up as an NS or a BH, rather than a WD. α Vir may well produce two NSs in due course, λ Tau probably only one NS and one WD. ϕ Per perhaps represents a late stage in the future evolution of α Vir, when Roche-lobe overflow has stripped the initially more massive star down to a hot remnant that is probably not very far from a supernova explosion. The longer period in ϕ Per is not inconsistent with a much shorter initial period, since conservation of angular momentum should tend to make the period increase as Roche-lobe overflow progresses. CV Ser might be the comparably late stage of a substantially more massive binary still, and arguably the more evolved but less massive component could be heading for a BH rather than NS. Although we argued earlier that a supernova explosion is likely to disrupt a binary, blowing the two components apart into separate single stars, it evidently does not always do this, since binaries such as QV Nor and Cyg X-1 have an NS and a BH companion respectively. These ultracompact companions are identified by the fact that they are highly luminous in x-rays (see X-RAY BINARY STARS). The BH is inferred in Cyg X-1 because, although its mass is not well known, it must on any reasonable model be several times higher than the maximum possible mass of an NS.

In both QV Nor and Cyg X-1 there is a normal star as well as a compact remnant. This normal component must itself grow with age, and lead to a second episode of Roche-lobe overflow. However, in these cases the mass ratio is very extreme, which by point (d) suggests a common-envelope phase with the likelihood that the orbit shrinks by a large factor. This may be the origin of a double-NS binary like 1913 + 16. No BH + NS binary has yet been recognized, but we can probably expect a small number of them in the Galaxy.

A rather large initial mass ratio seems required to produce a system like V404 Cyg, where one component is a BH while the other is a quite modest RG. Perhaps this started with a period as long as several years, with one star of 40 solar masses and the other of only 2 or 3. We know of no such systems directly, but they would be very hard to recognize. The more massive star may have briefly become an extreme RG, filled its Roche lobe and then suffered massive envelope ejection and simultaneous

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

orbital shrinkage by the common-envelope mechanism. The remnant of the massive star then collapsed in a supernova explosion to produce a BH, but, perhaps rather flukily, not disrupting the new short-period binary. Then the low-mass component evolved and now suffers Roche-lobe overflow. The RG should lose all its envelope, and end up as a WD: the result would be somewhat like the binary 1855 + 09, although with a BH rather than NS. To obtain 1855 + 09 itself, we might need moderately less massive original stars, but the history might be similar.

The science of understanding the evolutionary processes by which CB stars have reached the configurations in which they are observed is still in its infancy. By no means all of the small selection in table 1 fit comfortably with present understanding, and several much more difficult systems are known. To add to uncertainty, several stars turn out on close enough inspection to be triple, and the third star may be capable of interacting with the first two to give an extra layer of complexity.

Peter Eggleton

Close Binary Stars: Formation and Evolution

A binary system consists of two gravitationally bound stars that orbit their common center of gravity (COG). Observations indicate that the majority of stars are members of binary systems or even of multiple systems consisting of three, four or more stars. The multiple systems tend to be hierarchical, that is triples usually consist of a close pair with the third companion orbiting at much larger distance, etc. Single stars such as the Sun are less common. It is therefore impossible to develop a comprehensive theory of stellar evolution without including effects of binary evolution.

We speak of CLOSE BINARY STARS when the two stars are so close that they influence each other's evolution profoundly. Most commonly this is effectuated by the tidal forces (see below) by which the stars are deformed and, when one of the stars expands beyond a certain critical surrounding surface (ROCHE LOBE), cause mass exchange between the two stars. Since stars swell up considerably during their lifetime, often by several orders of magnitude, even binaries with orbital periods of decades can be close binaries. G P Kuiper (1941) was the first to recognize the importance of Roche lobes for binary stars. Close binaries can be classified into three broad classes: *detached* (D), *semidetached* (SD) and *contact* (C), depending on whether none (D), only one (SD) or both stars fill their critical Roche surface for mass exchange.

The prototype semidetached close binary system is ALGOL (β Persei); its periodic (2.87 days) brightness variations were first discovered in 1667 but it was only in 1783 that John Goodricke explained these variations in terms of an eclipse of one star by the other in a close binary system. After the introduction of stellar spectroscopy at the end of the 19th century this idea was shown to be correct. However, with the advent of stellar evolution calculations on electronic computers around 1950 the Algol system appeared paradoxical: how can the less massive ($0.8M_\odot$) subgiant component be further evolved than its more massive ($3.7M_\odot$) main-sequence companion? It was known that a more massive star always evolves faster owing to its higher central temperature and correspondingly faster rate of thermonuclear fusion. Furthermore, it was discovered that the subgiant components of Algol-type systems do not obey the usual mass–luminosity relation but that the luminosities and radii were significantly larger. In 1955 J A Crawford came up with the solution of the 'Algol paradox': initially the subgiant was the more massive component until it expanded beyond its Roche lobe and transferred a large fraction of its mass to the less evolved main-sequence companion. The currently observed peculiar subgiants in Algol-type systems are thus remnant stars that have lost most of their mass. Mass transfer between two stars is a basic feature of the evolution of close binary systems whereby very diverse systems can be formed. Obviously, the currently observed binary configuration depends on the binary's evolutionary phase and on its initial conditions (mainly the initial masses, orbital period and orbital eccentricity), i.e. on the primordial binary system. Obviously, these initial conditions are determined by the binary formation process which is, however, still shrouded in mysteries. Observations of PRE-MAIN-SEQUENCE BINARIES indicate that binaries are formed as a byproduct of star formation, but the details remain obscure.

In the past few decades, when satellite observations of cosmic UV and x-ray sources became available, much attention has been given to binaries which harbor compact stars. Large amounts of high energy are liberated by internal dissipation when the transferred mass falls into the deep potential well of a compact companion. Examples of such systems are the CATACLYSMIC BINARIES (white dwarf accretor) and X-RAY BINARIES (neutron star or black hole accretor).

Tidal deformation of binary stars

When the orbital separation D between two binary components is large compared with the dimension of the largest star, the dynamics of the two bound stars can be adequately described by a system of two point masses. However, when the size R of the largest star is not much smaller than the orbital separation D one has to take into account the internal structure of the star(s). The difference between the companion's attractive gravitational force at the close and the far sides of the other star is governed by Newton's inverse square law. The ratio between the companion's gravitational force at the two extreme points of both stellar hemispheres of the larger star is thus $[(D-R)/(D+R)]^{-2}$. This ratio can differ significantly from unity if R/D is not much smaller than unity. Clearly the mutual gravitational attraction not only keeps the two stars together in their orbit but also squeezes the stars by pulling them apart along the line connecting the two stellar centers. This deformation is a manifestation of the 'tidal force', i.e. the difference of the gravitational force over the star. If the orbit is eccentric and/or the stellar spins are not synchronous with the orbital revolution the tidal deformation of the close binary components is obviously time dependent. The decrease of orbital energy through inevitable dissipation of these periodic tidal deformations generates tidal torques between the stars that tend to circularize (and shrink) the orbit and tend to synchronize the stellar spins with the orbital revolution. The time scale for this tidal relaxation process declines rapidly with increasing R/D, i.e. with increasing tidal squeezing of the binary components. For sufficiently close binaries the tidal deformation of the stars can become so severe that surface matter in one of the stars (or both) becomes unbound and starts flowing off to the companion, a phenomenon known as *Roche lobe overflow* (RLO).

Principles of mass transfer in close binaries

Let us adopt the so-called 'Roche approximation', i.e. we assume that the tidal torques have acted sufficiently

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

long for the binary orbit to have become circular (i.e. both stars describe circles about their common COG). We also assume that, as a result of tidal torques, the stars spin about their individual COG with the same angular speed as the orbit. Because the internal mass distribution of stars exhibits a strong concentration to the stellar center (generally increasing with age) we may, as a first approximation for the gravitational field in the rarefied outer layers, assume that all the mass is concentrated at the stellar center. Let us now consider a test particle (i.e. a point mass with negligible mass compared with the stellar masses M_1 and M_2) drifting outside the two stars. Introducing a frame rotating with the same angular speed $\Omega = [G(M_1 + M_2)/D^3]^{1/2}$ as the orbital motion about the COG, we can express the acceleration experienced by this particle as:

$$\frac{\mathrm{d}\vec{v}}{\mathrm{d}t} = -\frac{GM_1}{r_1^3}\vec{r}_1 - \frac{GM_2}{r_2^3}\vec{r}_2 - \vec{\Omega} \times (\vec{\Omega} \times \vec{r}) - 2\Omega \times \vec{v}$$

where G is Newton's gravitational constant, $\vec{r}_1$ and $\vec{r}_2$ are the vectors from the two stellar masses to the test particle and $\vec{r}$ is the vector from the COG to the particle. The last two terms on the right describe the centrifugal and the Coriolis acceleration in our rotating frame. It can be shown that the acceleration of a co-rotating test particle (with $\vec{v} = \vec{0}$) can be expressed as the gradient of the effective gravitational potential (corrected for the centrifugal effect):

$$\Psi = -\frac{GM_1}{r_1} - \frac{GM_2}{r_2} - \Omega^2\frac{d^2}{2}$$

where d is the particle's distance to the orbital axis through the COG.

Surfaces of equal Ψ are known as Roche equipotential surfaces; see figure 1. The cross sections with the orbital plane contain five special points, called *Lagrangian points* L_1, $L_2, \ldots, L_5$, where the acceleration of the comoving particle vanishes, i.e. where the gravitational acceleration due to the two stars is precisely cancelled by the centrifugal acceleration away from the orbital axis. The equipotential surface through the inner Lagrangian point L_1 consists of two pear-shaped Roche lobes and forms the biggest closed surface around each of the two stars, merging at L_1. It can be shown that the Roche equipotential surfaces inside the stars coincide with surfaces of equal pressure and density: the Roche equipotentials (approximately) give the shape of the two stars in the binary. What happens if one of the two stars expands and fills its Roche lobe? We have seen that a test particle at rest in L_1 experiences no net acceleration. However, inside the lobe-filling star acts another force due to the gradient of the thermal pressure in the stellar gas. If the star is detached this pressure force balances the inward pull of gravity of the star (corrected for the centrifugal force due to the stellar spin). But since the net gravitational force (corrected for rotation) is zero in L_1 the pressure force there is unbalanced and blows a jet of gas through the (saddle point) region around L_1 into the the companion's Roche lobe. There it will be rapidly accelerated to supersonic speeds by the companion's gravitational attraction. The transferred mass (or at least a fraction of it) will ultimately fall onto the companion. As the mass flow through L_1 carries orbital angular momentum it cannot fall straight onto the companion and—if the latter is compact enough for the stream not to hit it directly—it will form an accretion disk around the companion in which part of the infall energy is dissipated and radiated away. The mass exchange profoundly alters the further evolution of both stars.

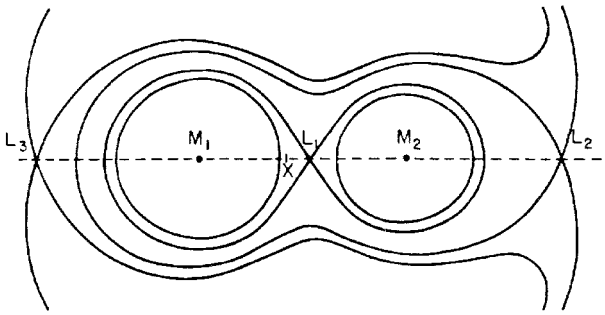

Figure 1. The cross section with the orbital plane of some special Roche equipotentials. The surface through the inner Lagrangian point L_1 forms the two Roche lobes around the stars. The cross denotes the binary's center of mass.

Orbital evolution

The process of mass exchange is a complicated hydrodynamic phenomenon the details of which are still poorly understood. The broad picture is as follows. Let us assume for simplicity that all the matter that flows into the companion's Roche lobe is ultimately accreted by the companion and that the system's orbital angular momentum

$$J_{\mathrm{orb}} = \left(\frac{GM_1^2M_2^2D}{M_1 + M_2}\right)^{1/2}$$

is *conserved* during the mass exchange. Part of the orbital angular momentum could be absorbed (through tidal torques) by the stellar spins but, except for extreme systems, this can usually be neglected. Because the amount of mass and angular momentum stored in the transferred, but not yet accreted, matter can be neglected relative to that of the two stars, the new orbital separation after exchange of a given amount of mass is given by the condition that J_{orb} is constant. If we differentiate the above expression with respect to time (indicated by a dot) then the condition $\dot{J}_{\mathrm{orb}} = 0$ yields

$$\frac{\dot{D}}{D} = -2\left(1 - \frac{M_1}{M_2}\right)\frac{\dot{M}_1}{M_1}$$

which shows that mass transfer from the more massive star (M_1) to the less massive star ($\dot{M}_1 < 0$) yields $\dot{D} < 0$ and thus gives rise to a *shrinking* orbit. On

the other hand, when $M_1 < M_2$ mass transfer to M_2 *widens* the orbit. Observations of many binary systems confirm this basic picture, although many of the details are still poorly known. For example, observations of circumstellar matter around SD close binaries indicate that some of the transferred matter may escape accretion by the companion. However, except in extreme situations, the assumption of no mass loss from the system seems generally to yield at least a qualitatively correct picture.

Response of mass-losing star

Since the more massive star (primary) in the binary has the largest radius and evolves fastest it will be the first to expand to its Roche lobe in initially detached close binary systems. We have just seen that the orbital separation D decays in response to mass transfer to a less massive component. The size of the Roche lobe around the primary shrinks with D and it depends on the primary's response to the loss of surface matter on what time scale the mass transfer is continued. This response depends on the stratification in the primary's envelope: a deep *convective envelope* is characterized by a steep temperature gradient. When mass is lost at its surface, rapid adiabatic expansion of the newly exposed surface layers—to restore global hydrostatic equilibrium—then brings up relatively hot material, making the star initially bigger than its thermal equilibrium configuration. On the other hand, when the envelope is predominantly *radiative*, for which the temperature gradient is less steep, adiabatic expansion causes the star to be smaller than its thermal equilibrium size. Obviously, RLO from a deep convective envelope is intrinsically unstable because the larger the mass loss, the stronger the rapid adiabatic expansion and the larger the primary's extension beyond the Roche lobe. Figure 2 shows the schematic evolution of a binary undergoing Roche lobe overflow (RLO). We can distinguish three time scales for the mass transfer.

Dynamical time scale mass exchange occurs when the primary's quick adiabatic response to the mass loss brings the primary's surface beyond the shrunken Roche surface. The primary cannot be kept inside its Roche lobe, so that its surface layers will be depleted by continuous expansion through L_1. This situation occurs when the primary is a (super)giant and has a deep convective envelope. A similar unstable situation occurs when the (more massive) contact star is degenerate (a white dwarf) because such stars always expand when losing mass.

Thermal time scale mass exchange occurs when after the quick adiabatic expansion that restores global hydrostatic equilibrium the primary remains inside its shrunken Roche lobe and no runaway mass exchange takes place. The mass transfer is then driven by the primary's (slower) thermal relaxation: by restoring thermal equilibrium in its perturbed outer layers the star will re-expand beyond its Roche lobe. This type of Roche lobe overflow occurs in primary's with (predominantly) radiative outer layers and is self-regulating because the thermal relaxation and consequent expansion compete with the shrinking due to rapid mass loss.

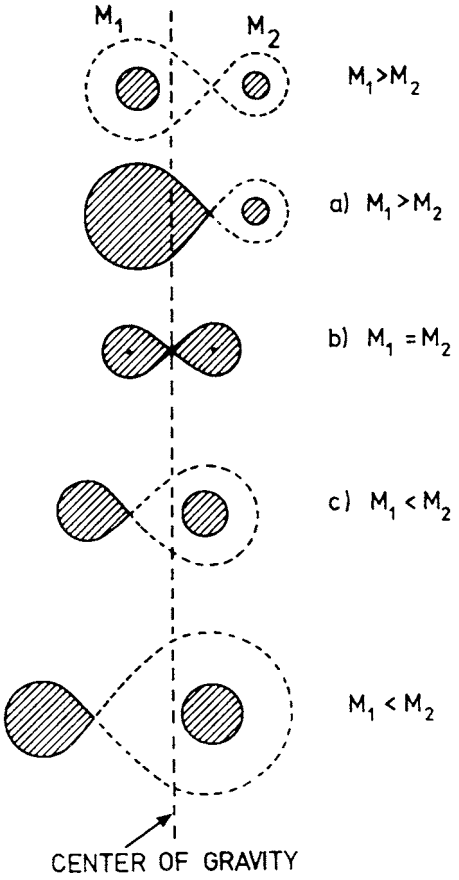

Figure 2. Subsequent stages of evolution of a close binary system in which the primary at the onset of RLO (in frame (*a*)) has a predominantly radiative envelope. In the upper frame the star expands on a nuclear time scale towards its Roche lobe. The phases (*a*) and (*b*) correspond to rapid thermal time scale mass transfer which terminates at (*c*). From then on the binary expands and mass transfer occurs on the intrinsic evolutionary expansion time of the now less massive contact star.

Nuclear time scale mass exchange occurs when the contact star is less massive than the accretor and the binary separation and generally the Roche lobe widen. Under these circumstances mass exchange can only be sustained by the primary's evolutionary expansion driven by thermonuclear fusion reactions in its interior. This situation occurs in the later phases of mass transfer after the mass ratio of the binary has been reversed and yields the slowest mode of mass exchange.

Response of accreting companion

Let us now consider what happens to the accreting secondary during incipient RLO. Being the less massive star in the system the accreting detached companion generally has a longer thermal time scale than the contact star. Therefore its thermal equilibrium becomes

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

severely perturbed by the rapid accretion of the transferred material, especially because the accreted material carries significant kinetic energy after falling down from L_1. This kinetic energy is mostly dissipated at or near the accretor's surface, heating it considerably. The (generally) small fraction of the orbital angular momentum carried along by the accretion stream can bring the accretor in rapid rotation. It is likely that the accretor will swell up to or beyond its Roche lobe, especially during a dynamical time scale mass transfer phase, but possibly also during a thermal time scale exchange. In that case the binary soon evolves into a contact system with a common envelope around the two Roche lobes. The subsequent evolution of such contact systems is poorly understood.

Cases A, B and C of mass exchange

There exist three main evolutionary phases during which a star expands and may first fill its Roche lobe, namely the phase of core hydrogen burning (main sequence phase) and the phases of rapid core contraction towards helium ignition and towards carbon ignition. Kippenhahn and Weigert (in 1967) introduced the corresponding classification into respectively cases A, B and C of mass exchange.

Case A. The primary fills up its Roche lobe while still on the main sequence. Once Roche lobe overflow begins the primary's thermal equilibrium becomes increasingly perturbed and a rapid phase of thermal time scale mass exchange follows by which the mass ratio q is more than reversed. After that the evolution slows down to a nuclear time scale. The Roche lobe filling star has become an overluminous core hydrogen burning subgiant. Many eclipsing variables of this type are known. Numerical simulations show that case A mass exchange almost always leads to a contact binary.

Case B. The primary is a (sub)giant burning hydrogen in a shell when it reaches its Roche lobe. The initial rapid phase of mass transfer can either be on a dynamical time scale (when the primary has developed a deep convective envelope) or on a thermal time scale when the convection in the envelope is less developed. The subsequent slower phase of mass transfer to the now more massive companion proceeds either on the thermal time scale of the contracting helium core or on the nuclear time scale of the hydrogen shell source in the less massive primaries that have developed a compact electron degenerate helium core.

For primaries originally more massive than $\simeq 3M_\odot$ the mass exchange terminates when the primary ignites helium in the core whereby the remnant of the primary (almost stripped of its hydrogen envelope) shrinks inside its Roche lobe. Case B in massive binaries thus produces almost pure helium stars (WOLF–RAYET STARS (WR stars)) in orbit with a main sequence companion. The more massive helium stars (roughly $M_{\rm He} > 2.5M_\odot$) subsequently explode as a type II supernova: the remnant core collapses to a neutron star, or even a black hole.

Primaries originally less massive than $3M_\odot$ terminate the rapid mass transfer phase when the stellar expansion slows down with the onset of electron degeneracy in the highly compressed helium core. The subsequent slow mass exchange produces binaries with mass ratios as small as 1/5 or 1/10. The main sequence secondary is now much brighter than its less massive (overluminous) subgiant contact companion. If the orbital inclination is favorable such a binary system shows eclipses and will be classified as an Algol-type binary. The mass transfer terminates when the contact star's hydrogen envelope is depleted by both shell burning and mass loss. The remnant envelope shrinks within its Roche lobe and the primary evolves into a low-mass helium white dwarf.

Case C. This corresponds to mass transfer from evolved stars with very extended envelopes and has been little studied partly in view of the difficulties in treating the extended cool outer layers of the contact star.

Figure 3 shows the orbital period values that correspond to the three classes of mass exchange for a binary consisting of a $7M_\odot$ plus $3M_\odot$ (or $5M_\odot$) star. To compare the size of the Roche lobe with the usually spherical stellar models one determines the Roche radius: that is the radius of a sphere with the same volume as the Roche lobe.

Non-conservative evolution of binaries

We have already noted that part of the mass stream through L_1 in semidetached binaries may leave the system, but so far we have no means to quantify this reliably. However, there exist other ways by which mass may be lost from a binary. Observations show that many stars lose mass in the form of stellar winds, independent of a possible binary companion. The companion may in fact capture part of this ejected wind material, so that mass exchange can occur even in detached binaries. However, the transfer rates are generally much smaller than for RLO. In (super)giant stars and very massive early-type stars the stellar wind losses take away a significant fraction of the star's mass. A fast isotropic wind which decouples from the star at its surface leaves the angular momentum of the remaining mass invariant and thus widens the binary orbit as the gravitating mass in the binary decreases.

Stars with surface magnetic fields strong enough to couple to the ejected ionized wind material and enforce corotation out to several stellar radii from the surface are spun down by the magnetic torque. In SD binary systems effective tidal interaction tends to keep the stellar rotation synchronous with the orbit, so that the spin angular momentum carried off by the magnetically coupled wind must be compensated by the system's orbital angular momentum. An effectively coupled wind can thus enforce a decrease of the orbital separation. If these wind losses can occur simultaneously with RLO the mass transfer rate is enhanced by the induced shrinking of the Roche lobe. It is commonly believed that such '*magnetic braking*' occurs in systems with G- and K-type stars, e.g. in cataclysmic

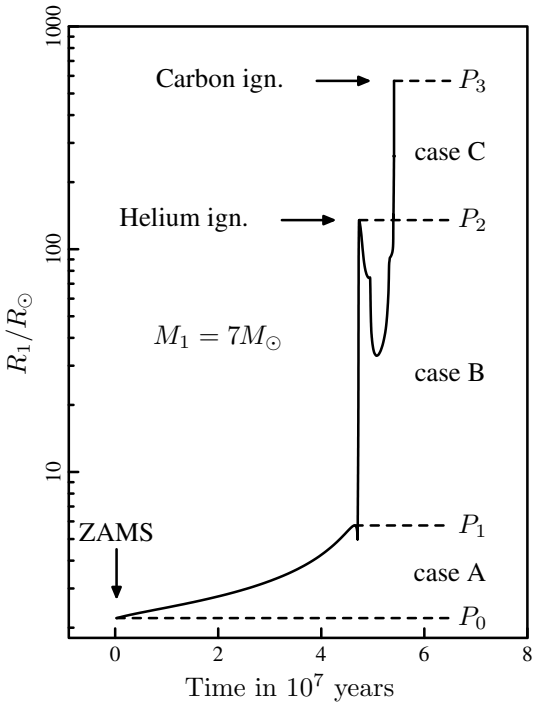

Figure 3. The radius expansion of a $7M_\odot$ star defines the critical orbital periods for the three cases A, B and C of RLO. The size of the Roche lobe is determined by the mass ratio M_1/M_2 and the orbital period (separation). A binary with an orbital period as short as P_0 would be semidetached from the very beginning of its main sequence phase. For a $3M_\odot$ ($5M_\odot$) companion the critical periods are (in days): $P_0 = 0.52$ (0.47), $P_1 = 2.2$ (2.0), $P_2 = 247$ (225) and $P_3 = 2137$ (1951). For an initial period of say 50 days the binary would evolve as case B: the primary would fill its Roche lobe after exhaustion of hydrogen in the core.

variables (CVs). The observationally inferred spin-down of G stars with age gives us information about this magnetic braking although it is not at all certain that these values may be applied to rapidly rotating binary stars.

Another non-conservative effects follows from Einstein's general theory of relativity which predicts that a compact binary system emits *gravitational radiation* carrying off angular momentum. The resulting rate of orbital angular momentum loss is

$$\frac{\dot{J}}{J} = -\frac{32}{5}\frac{G^3}{c^5}\frac{M_1 M_2}{D^4}(M_1 + M_2)\,\mathrm{s}^{-1}$$

where c is the speed of light. In close binaries with orbital periods less than about half a day the induced orbital decay becomes significant.

Common envelope binaries

Little is known about the transfer of mass and energy between two stars in contact binaries and their evolution cannot be simulated reliably. The best known class of contact binaries are the W Ursae Majoris (W UMa) systems which consist of stars of spectral type G and K, with a typical mass ratio of 2. These stars have convective outer layers and thus a convective common envelope which is thought to engulf the Roche lobes of both stars and to lie inside the equipotential surface through L_2. Contact binaries with massive early-type stars (which have radiative envelopes) are also observed. Furthermore there is observational evidence for contact binaries with cool supergiant components with deep convective envelopes.

Spiral-in evolution

It was suggested by B Paczynski (in 1976) and is now commonly believed that, under certain circumstances, the evolution of common envelope binaries can be very violent in contrast to the observed, apparently stable, systems mentioned above. A critical factor seems the binary's mass ratio $q = M_1/M_2$. If the contact star in a close binary is much more massive and bigger than its companion it will absorb a non-negligible fraction of the orbital angular momentum when tidal forces try to keep its spin synchronous with the speeding up of its companion's narrowing orbital revolution. Even before the SD phase the natural expansion of the primary slows down its spin whereby tides become active to resynchronize the star. Because of the primary's absorption of orbital angular momentum the companion must spiral slightly inward after which it revolves even faster in its orbit. In order to speed up the spin of the big star towards synchronism ever more angular momentum needs to be tapped from the orbit and for a sufficiently big primary the binary undergoes a catastrophic tidal instability (G H Darwin, 1908) whereby the companion dives into the primary's envelope. The companion then moves with supersonic speeds through the primary's envelope whereby shock waves violently dissipate orbital energy, leading to even faster orbital decay. The details and precise outcome of this complicated phenomenon are unknown. In many cases the primary's envelope may be expelled by the dissipated orbital energy, so that virtually only its core remains in a tight orbit with the perhaps ablated companion. The observed planetary nebulae with double cores (about 5–10% of the population) may be the result of such evolution. Another observational link exists, namely with the CVs, compact binaries with a white dwarf component which is surrounded by a luminous accretion disk. These systems show weak periodic outbursts (dwarf novae) or strong eruptions (novae).

Formation and evolution of CVs

CVs are thought to have evolved through a spiral-in phase because the WHITE DWARF component must be the remnant core of a former big giant star which can never have been accommodated in the currently observed tight CV binary systems with typical orbital periods less than 10 h. Presumably the unevolved main-sequence companion of the white dwarf, originally in a wide orbit, spiralled into the much bigger and heavier giant (white dwarf progenitor) owing to a tidal instability and evaporated the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

latter's extended envelope, so that only the degenerate core (white dwarf) remained. For orbital separations (just after the spiral-in phase) larger than a critical value the binary evolves slowly to a wider system when the unevolved star expands to its Roche lobe and a slow nuclear time scale mass transfer sets in. In the narrower systems magnetic braking of the main-sequence star is thought to dominate, whereby the binary separation decays even when the main-sequence star fills up its Roche lobe and transfers matter to the more massive white dwarf. The enhanced mass transfer generates a hot, luminous accretion disk around the white dwarf and the binary has become a CV.

The magnetic braking time scale being much shorter than the contact star's nuclear time scale, the nuclear evolution of this star is effectively frozen and it evolves down the main sequence, remaining roughly in thermal equilibrium. However, when the orbital period has been decreased to about 3 h the continuing mass loss has mildly perturbed the contact star's thermal equilibrium. Observations indicate that no CV binaries exist with a period between roughly 3 and 2 h: the so-called *period gap*. The period gap is believed to be caused by the sudden termination of magnetic braking with consequent interruption of mass transfer as the star shrinks inside its Roche lobe as it restores thermal equilibrium. It is thought that magnetic braking terminates when the contact star has become fully convective—which occurs roughly at this stage of evolution in numerical simulations. By then the only angular momentum losses from the binary are due to gravitational radiation.

Only when the orbit has decayed and the Roche lobe has tightened again around the low-mass star can the RLO continue. When continuing RLO has reduced the contact star's mass to about $0.1M_{\odot}$ its thermal time scale becomes longer than the time scale for mass loss, i.e. longer than the time scale for gravitational radiation losses. Further mass loss perturbs its thermal equilibrium significantly and the star evolves away from the main sequence. At this time the nuclear fusion reactions in its interior begin to fade, whereby the electron gas becomes degenerate. After a while the contact star becomes so degenerate that its mass–radius relation reverses and it begins to expand in response to any mass loss. From then on the mass transfer rate is dictated by the condition that the Roche lobe, and thus the stellar separation, must increase. The binary system thus passes a *minimum orbital period* which, for hydrogen rich envelopes, turns out to be about 80 min. The observed absence of CV systems below $P_{\rm orb} \simeq 80$ min confirms that the mass transfer in these compact CVs is indeed driven by gravitational radiation.

Formation and evolution of high-mass x-ray binaries (HMXBs)

Massive x-ray binaries consist of a massive, early-type (OB) star in orbit with a NEUTRON STAR which captures matter from the massive star's stellar wind through gravitational focusing. The existence of a neutron star implies that the binary survived a violent SUPERNOVA (SN) explosion by which the neutron star was formed after the collapse of the primary's burnt out stellar core. It is believed that before the SN explosion the binary evolved through a case B mass transfer by which the mass ratio reversed, so that the helium star remnant of the primary had become the less massive component when it exploded as a SN (van den Heuvel and Heise, 1972). Had it been the more massive star that exploded the binary would have been dispersed, unless the explosion was asymmetric and happened to generate the right net kick in the direction opposite to the orbital motion so that the binary could survive.

In the *Bondi–Hoyle* approximation the neutron star's effective wind interception radius is $R_A \simeq GM_2/V^2$, where V is the velocity of the (supersonic) wind material near the neutron star (in its rest frame). For typical wind speeds R_A is larger than the neutron star's geometric radius. The wind velocities are high, of order the escape speed from the primary's stellar surface, so that the companion can accrete only a small fraction of the emitted wind. The wind matter heats up and emits x-rays when it collides with the neutron star, producing a bright x-ray source (e.g. Vela X-1); this corresponds to stage (*e*) in figure 4. In some cases (Cen X-3) incipient RLO may be responsible for the x-ray emission, although full-blown thermal time scale mass transfer from the massive star presumably leads to disappearance of the x-ray source by self-absorption and to a subsequent spiral-in of the neutron star and evaporation of the massive star's envelope. The spiral-in may produce a new, but now much more compact, x-ray binary system like Cyg X-3 with an orbital period of only 4.8 h, corresponding to stage (*g*) in figure 4. Infrared spectroscopy has shown that the companion of the neutron star is a nitrogen-type WR star. Such stars are helium stars with masses in excess of about $5M_{\odot}$, so that the helium star in Cyg X-3 is probably the bare core remaining after spiral-in of the neutron star into the much more massive original secondary. When the second helium star has evolved to the SN phase the binary may be disrupted, leaving two single neutron stars in which the youngest, because of its rapid spin and strong magnetic field, acts as a radio pulsar. If circumstances are favorable (supernova kick) and the binary remains bound, we are left with a compact binary pulsar system, of which several are observed and in which the orbital decay by gravitational radiation can be accurately measured because of the accurate clock provided by a rapidly spinning neutron star (radio pulsar). Observations by J H Taylor (in 1986) beautifully confirmed the prediction from general relativity.

Formation and evolution of low-mass x-ray binaries (LMXBs)

Our Galaxy contains about 100 low-mass x-ray binaries in which the neutron star (or BLACK HOLE) receives mass from a low-mass contact star. Figure 5 shows a typical HMXB and LMXB system. Only for a minority of these systems has the orbital period been measured; most orbital periods turn out to be less than 20 h. However, from

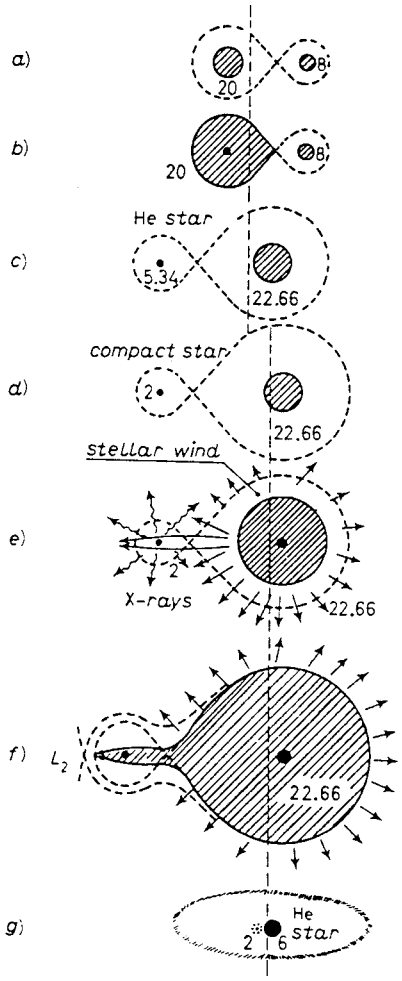

Figure 4. Stages in the evolution of an HMXB. It is assumed that the SN explosion of the primary leaves a $2M_\odot$ neutron star: (*a*) $t = 0$, $P = 4.7$ days; (*b*) $t = 6.17 \times 10^6$ yr, $P = 4.7$ days, onset of RLO; (*c*) $t = 6.20 \times 10^6$ yr, $P = 10.86$ days, end of RLO and beginning of WR phase; (*d*) $t = 6.76 \times 10^6$ yr, $P = 12.63$ days, He star (WR star) has exploded as an SN; (*e*) $t = 10.41 \times 10^6$ yr, $P = 12.63$ days, the normal star becomes a supergiant and its strong stellar wind powers a bright x-ray source; (*f*) $t = 10.45 \times 10^6$ yr, $P = 12.63$ days, onset of second phase of RLO, x-ray source disappears owing to absorption, followed by a spiral-in of NS; (*g*) $t \simeq 10.47 \times 10^6$ yr, $P \simeq 4$ h, onset of second WR stage. Finally, at $t \simeq 11 \times 10^6$ yr, the second He star explodes as an SN; survival or disruption of binary pulsar depends on remnant mass and the possible kick from the SN explosion. (After van den Heuvel.)

the existence of wide binaries consisting of a radio pulsar with a white dwarf companion one expects the existence of LMXBs in which the neutron star is powered by RLO from the expanding (sub)giant progenitor of the white dwarf, a phase during which the binary widens on the nuclear time scale of the (sub)giant. Few of these systems are observed but Cyg X-2 probably belongs to this class. Like in CVs, the observationally inferred mass transfer rates in *compact* LMXBs seem higher than can be driven by

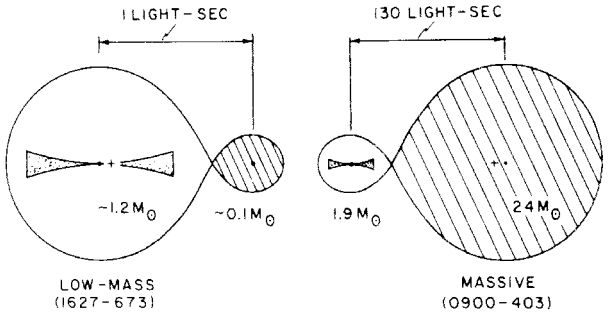

Figure 5. Comparison of the very different dimensions of a low-mass x-ray binary and a high-mass x-ray binary. The optical stars are depicted to fill their Roche lobes (hatched). The radial extent of the accretion disks (stippled) around the neutron stars is sketched nearly to scale. The dots and the crosses (+) mark the centers of mass of the individual stars and the system, respectively. (After Bradt and McClintock.)

the slow nuclear expansion of the low-mass contact star. Apparently the mass transfer is enhanced by the angular momentum loss driven contraction of the binary, like in CVs. It appears there is a *bifurcation* into compact and wide LMXBs: short-period systems, in which magnetic braking and gravitational radiation driven angular momentum losses dominate, evolve to ever smaller size, while systems with periods beyond a critical initial period (of order 1 day), beyond which these angular momentum losses become ineffective, evolve on the nuclear expansion time of the (sub)giant contact star and become very wide systems. A major difference between compact LMXBs and CVs is that accretion onto the neutron star in LMXBs liberates far more energy which may be partly intercepted by the (thus heated) contact star. The accreting matter can spin the neutron star up to millisecond spin periods. It has been suggested that the accreted rotational energy may ultimately *evaporate* the low-mass contact star in compact LMXBs. That would explain the apparent absence of the (orbital) period gap between about 3 and 2 h in LMXBs which is seen in the population of CVs. The idea is that after termination of magnetic braking (when the contact star becomes fully convective) the mass transfer is interrupted, so that the neutron star is suddenly unveiled and becomes a rapidly spinning *radio pulsar* whose high-energy emission may evaporate the companion before it refills its Roche lobe. This evaporation would also explain the observed existence of rapidly spinning single-millisecond radio pulsars.

From the fact that our Galaxy contains a similar number of HMXBs (only 50% less than the number of LMXBs) whereas the lifetime of a HMXB must be orders of magnitude shorter than that of an LMXB, we can deduce that the formation of an LMXB is a much rarer event than the birth of an HMXB. Therefore it is no surprise that the formation of LMXBs is far less straightforward than that of HMXBs. One of the formation scenarios that have been suggested is *accretion-induced collapse* (AIC)

Dirac House, Temple Back, Bristol, BS1 6BE, UK

of a massive white dwarf, whereby the white dwarf is driven over the *Chandrasekhar limiting mass* and collapses to become a neutron star. This process requires precise fine tuning with mass transfer rates in a narrow range to a rare sort of massive white dwarf (consisting of O–Ne–Mg). Such white dwarfs can only be formed in binaries with a restricted range of primary masses and orbital periods. Mass transfer to more common intermediate-mass carbon–oxygen white dwarfs leads in most cases to explosive carbon burning by which the degenerate star is completely destroyed in a type Ia SN explosion.

Some LMXBs have black hole companions (see BLACK HOLE CANDIDATES IN X-RAY BINARIES) and these cannot be produced by AIC, so that formation channels different from AIC must be active in producing LMXBs. In the special high star density environment of globular clusters LMXBs may be formed when a low-mass main-sequence star is captured by a passing compact star, but this cannot explain the occurrence of LMXBs in the rest of the Galaxy. Spiral-in evolution after an SN explosion of a massive helium star might explain the existence of neutron star or black hole components in compact LMXBs, but only under rather extreme conditions can the post-spiral-in systems evolve into LMXBs.

Clouds in Planetary Atmospheres

What are clouds? The answer to that question is both obvious and subtle. In the terrestrial atmosphere clouds are familiar as vast collections of small water drops or ice crystals suspended in the air. In the atmospheres of Venus, Mars, Jupiter, Saturn, Saturn's moon Titan, Uranus, Neptune, and possibly Pluto, they are composed of several other substances including sulfuric acid, ammonia, hydrogen sulfide, ammonium hydrosulfide, methane, and complex organic molecules. The study of clouds touches on many facets of atmospheric science. The chemistry of clouds is tied to the chemistry of the surrounding atmosphere. Clouds can be both a source and a sink for condensable molecules as they moisten or dry the air. Local cooling or heating and local differences in moisture content due to cloud formation change the buoyancy of air parcels which drives local dynamics (frontal systems, thunderstorms and hurricanes are a few familiar examples). Clouds influence the global climate by reflecting or absorbing solar radiation while trapping thermal radiation. The fate of life on Earth a few centuries from now may hinge on their uncertain role in mitigating the greenhouse effects of increased emission of carbon dioxide gas from biomass and fossil fuel burning. This article examines what we know about clouds in the atmospheres of the planets.

Cloudy planetary atmospheres

Saturn's largest satellite Titan and all the planets except Mercury have cloudy atmospheres (see PLANETARY ATMOSPHERES). These can be categorized into three main groups. Water is the principal cloud constituent on the relatively thin atmospheres of Earth and Mars. Venus and Titan have thick cloud and haze layers which are influenced strongly by chemical reactions initiated by sunlight in the high atmosphere. The giant planets Jupiter, Saturn, Uranus and Neptune have reducing atmospheres dominated by hydrogen which combines with trace amounts of nitrogen, sulfur and carbon to form clouds of ammonia (NH_3), ammonium hydrosulfide (NH_4SH), hydrogen sulfide (H_2S) and (for Uranus and Neptune) methane (CH_4). Methane clouds were inferred to be present in Pluto's atmosphere although the interpretation of the data is ambiguous.

The Earth

We know most about the nature of clouds in the EARTH'S ATMOSPHERE and so it is instructive to begin a survey of planetary clouds with a review of terrestrial clouds. Water is by far the main constituent of terrestrial clouds but some other constituents (mainly sulfur and nitrogen) are often present. Water can exist as vapor, liquid drops, or frozen ice crystals. The amounts of water in these various forms depends on the complex history of each air parcel as it moves over land or water. Clouds take on characteristic forms which are controlled by the dynamical processes responsible for their formation. By looking at photos of clouds taken from space a sense of the dynamical regime can be revealed.

Visual categorization of cloud types is a science that goes back many hundreds of years, and much of the terminology is Latin. Meteorologists in the present day group clouds into three main groups depending on the altitude (low, middle and high), with sub-categories within each group. In the lowest 2 km altitude are the cumulus, cumulonimbus, stratus, stratocumulus, and nimbostratus. Within the middle layer (2–8 km) are altostratus and altocumulus. At the highest level in the troposphere are cirrus, cirrostratus and cirrocumulus. At still higher altitudes in the stratosphere and at very low concentrations (except immediately after a volcanic eruption) are small sulfuric acid drops at many latitudes and ice particles which form the polar noctilucent clouds (thin clouds seen in the polar dawn and dusk).

Cumulus clouds are relatively small (a few km in diameter), detached, puffy clouds whose tops and sides appear brilliant white in direct sunlight. In this form they would be impossible to see from space unless observed with a nearby camera with high spatial resolution. They can be seen as single clouds, in fields of many, and may develop into large towers of several grouped together. As moisture becomes more available from ground evaporation these clouds can grow and merge to form cumulonimbus which are heavy and dense, with a towering structure. These can be sites of precipitation and lightning. As seen from above they often show a flat top with a tail extending downwind. The morphology of the tail appears similar to a blacksmith's anvil, and the word 'anvil' is often applied to these features. The clouds are classified as low clouds because the base is within the lowest level, but in its entirety the cloud extends through all three levels, with the anvil providing a source of water downstream in the highest level.

Stratus clouds form a fairly flat, uniform layer, dark gray blanket when seen from below. They often produce drizzle or snow. Stratocumulus appear much like stratus except that they show detail (patchiness, ragged edges) and are less dense in places, permitting more sunlight to penetrate and showing a lighter shade of gray. Seen from above, they appear clumpy and sometimes reveal periodic roll structures (cloud streets) which can extend for many kilometers. Motion within these clouds can occasionally produce cumulus-type structures. Large (~1000 km) banks of stratus and stratocumulus clouds can be seen in satellite photographs. Nimbostratus can be extremely deep with a top nearly at the top of the troposphere and usually produce precipitation.

Altostratus clouds are distinguished from stratus mainly by the location of their base which is higher in the troposphere. A colored corona around the Sun can sometimes be seen. This is a consequence of the way ice crystals scatter light. Altocumulus also have their base higher in the atmosphere compared to cumulus. These clouds are usually thin and may take on a multitude of

Dirac House, Temple Back, Bristol, BS1 6BE, UK

forms from thin and flat to detached clumps to castle-shaped morphology.

Clouds in the high troposphere are composed almost entirely of ice particles. By analogy with the lower clouds, the clouds which are confined to the highest layers (cirrus, cirrostratus, and cirrocumulus) can range from broad flat sheets to clumpy, distinct elements. There are many sub-categories of cirrus which characterize the many ways these clouds can appear (smooth, stranded, with hooks, in cells, grainy or undular, resembling skeletal structures, etc). All of this morphological richness is rooted in the equally rich dynamic wind field and a complex interplay between the supply of vapor or crystals, and cloud microphysical processes (nucleation, condensation, growth, evaporation, aggregation, precipitation). Much of the cirrus owes its origin to water supplied by high altitude entrainment of air from upstream cumulonimbus anvils and nimbostratus cloud tops. Atmospheric halos and coronae are often seen within thin cirrus clouds, a result of sunlight scattered by large water ice crystals.

How do we understand the complexity of the different cloud types and what do they tell us about the processes? This is an area of active research but already a great deal is known. The existence of a cloud points to a process where an air parcel containing water vapor (say, from evaporation over the ocean or over moist land surface) was transported to a location where the temperature is cooler—cool enough that the vapor pressure of water in the air is higher than the condensation vapor pressure at the air temperature. In the lowest 12 km or so altitude (the troposphere) the temperature decreases with altitude, so a parcel of moist air which buoyantly rises from the ground will eventually reach a level where the temperature is cool enough to support condensation and cloud formation. Low-lying clouds have so much moisture that they need not rise very far for the temperature to reach the condensation temperature. Another way to cool the air and promote cloud formation is to mix warm moist air with cool dryer air as a polar cold front moves through. A third way is to lift air as it flows over a mountain. A cloud forms above or nearby a mountain when the air flowing over cools as it reaches a higher altitude. Clouds formed in this way are called orographic clouds because they remain fixed next to a topographic feature as the air flows past. The same process operates in the Martian atmosphere near the tops of the high volcanos and in Neptune's atmosphere above a large vortex (the Great Dark Spot).

Cumulus cloud formation is initiated by natural convection as sunlight warms a moist ground. As a warm, moist buoyant parcel of gas rises it reaches a condensation level where the temperature drops below the condensation temperature and the cumulus cloud forms at its base. An aid to convection in the terrestrial atmosphere is the density difference due to both the temperature difference (a warm parcel is less dense) and a compositional difference (a moist parcel is less dense than dry gas for the Earth's atmosphere). In the giant planet atmospheres a moist parcel is more dense than dry gas which inhibits rather than promotes moist convection. A third factor which enhances moist convection is the additional heat released as latent heat of condensation when the vapor condenses in the cloud. In a quiescent situation where cumulus or stratus clouds form and dissipate at an equal rate there is an equilibrium between the supply of moist air from the ground and evaporation and precipitation in the cloud. If there is a great deal of moisture available from the ground and if the initial convective motion is quite vigorous an instability can grow, with the buoyancy carried by the moist convective parcels amplifying to the point that very large amounts of moisture are injected at very high altitudes (cumulonimbus towers and anvils). Stratus clouds result from a more sluggish dynamical regime where the air is more stable and where there is a stable and abundant supply of moisture to maintain the cloud against precipitation and evaporation.

Space-based views of clouds on all the planets are dominated by the large-scale features. At large scales three types of cloud features are commonly seen in the Earth's atmosphere. Each of them has an easily recognizable morphology and motion which are rooted to the dynamical regime forcing cloud formation. Mesoscale convective systems consist of fields of cumulonimbus clouds whose anvils merge into a single cloud shield with a horizontal extent much larger than the individual anvils. Mesoscale convective systems may be long (~100 km) and narrow (a few km) with extensive precipitation occurring over a large scale. *Cumulus convection* is driven by small-scale (100 km or less) convective cells. Small-scale cells can combine to form the much larger mesoscale convective systems seen in satellite images.

Of special importance for the dynamics of the terrestrial atmosphere is the organized deep convection near the equator. Time-averaged maps of cloudiness reveal a band near the equator that moves in latitude with the seasons. This is the Inter Tropical Convergence Zone (ITCZ). Its existence is prompted by converging air mass at low altitude driven by large-scale Hadley circulation in both hemispheres. Abundant water vapor near the surface is available for a massive amount of latent heat transport. Moist convection within the ITCZ is vigorous and is responsible for a large amount of heat and moisture transferred to the upper atmosphere within the ITCZ.

Atlantic hurricanes and Pacific typhoons are tropical cyclones which constitute another commonly observed large-scale cloud structure. They form over oceans and derive their energy from moist warm tropical ocean air. Cyclones rotate in the counterclockwise direction in the northern hemisphere with lifetimes of the order of 10 d. Hurricanes and typhoons have return flow in a narrow column at the core which is free of clouds. There remains some controversy about what special conditions are required to transform commonly occurring tropical cyclones into intense systems that occur relatively rarely. A common thread to the various models involves a very effective coupling between cumulus-scale moist

Figure 1. The Solid State Imaging camera on the Galileo Orbiter captured this image of clouds over the southern Pacific ocean and Antarctica on 12 December, 1990 when the spacecraft was 1.6 million km from Earth. Extensive cloud formation can be seen, with prominent curved cloudy frontal systems associated with extratropical cyclones. The dark ocean provides the contrast which makes the clouds easy to see in visible-wavelength images. Clouds and surface ice are difficult to distinguish due to lack of contrast. In broad-band visible wavelengths there is no way to get a sense of cloud altitude, and the cloud type categories developed from ground-based experience are not apparent.

convection with the large-scale wind field via an instability called the conditional instability of the second kind, or CISK. According to most models the ocean surface temperature must be at least 26 °C, which agrees with observation and leads to the conclusion that these intense storms will be more frequent and/or more intense should the sea surface warm in the future from global warming.

A third commonly observed large-scale cloud structure is the extratropical cyclone which produces extensive precipitation in the middle latitudes. Several of them can be seen in figure 1. They are familiar as weather fronts ahead of cold low-pressure regions . The clouds that form at these fronts do so by *sloping convection* (as opposed to cumulus convection described above). Sloping convection occurs when one body of air overrides another, forcing moist air upward. Clouds of all types are associated with these large-scale features and also with the two others mentioned above.

With that brief introduction to terrestrial clouds we are now in a position to explore clouds on other planets. The best place to begin is with the atmosphere of Mars which contains water ice clouds and displays many of the dynamical features familiar to terrestrial meteorology (see MARS: ATMOSPHERE).

Mars

Our knowledge of the Martian atmosphere is based on images and spectra taken over many years from ground-based observatories as well as the Hubble Space Telescope, several Soviet and US flyby or orbiting satellites, and landers, most notably Mariners 4, 6, 7 and 9, Mars 2, 3, 4 and 5, Viking 1 and 2, Phobos 1 and 2 and Mars Global Surveyor, with more on the way or planned. As of the beginning of 1999 three craft (VIKING Landers 1 and 2 and MARS PATHFINDER) have landed on the surface and sent back *in situ* information on atmospheric composition, temperature, pressure and cloud and dust opacity. Many more landers are planned for the next decades.

The Martian atmosphere is made up almost entirely of carbon dioxide (CO_2) with trace amounts of water, argon and several other constituents. Mean surface pressure is 8 mb (compared to a pressure near 1 b at sea level on Earth). Surface temperature varies between about 140 K and 250 K depending on latitude and season. Carbon dioxide condenses to form an extensive frost layer on the surface of Mars at high latitude when the surface temperature drops slightly below 150 K. Occasionally the temperature in the polar atmosphere several km above the surface drops low enough to form a CO_2 ice haze, but almost all the bright white clouds seen on Mars are composed of water ice.

Water ice also condenses at high latitude during winter, and at lower latitudes as well during the cold night. The polar ice caps and the Martian soil serve as reservoirs of water which absorb or release water on diurnal and seasonal cycles as well as on much longer-term cycles tied to slow changes in the Martian orbit and tilt. Outflow channels on the surface are now dry but point to a much wetter Mars in the distant past. The present amount of water in the atmosphere amounts to only about 10 precipitable micrometers on average, too little to be important as a source of buoyancy via latent heat release. Thus none of the terrestrial cloud types (cumulonimbus or stratonimbus on the small scale, hurricanes and mesoscale convective systems) which feed on latent heat release and an abundant supply of water are seen on Mars.

The most fruitful approach to understanding water clouds on Mars is to note their similarity to cirrus clouds in the high, cold terrestrial atmosphere, with the addition of the effects of topography operative in the Mars atmosphere. Lee wave clouds are often seen on Mars downstream of high volcanic mountains and near craters at lower elevations. It is common to see lee wave clouds with many linear undulations extending for more than 100 km downstream. Clouds form most often in the early morning and late afternoon when the temperatures are cool. They are abundant in northern summer in the Tharsis region, a high plateau home to several of the highest Martian volcanos. Figure 2 shows this, along with large-scale features that appear to trace planetary-scale Rossby waves at high latitude much as do extratropical cyclone

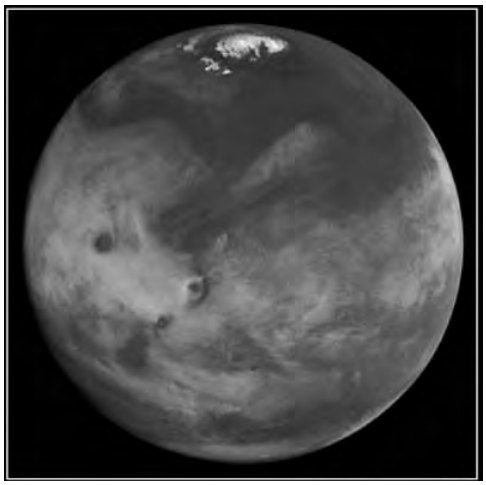

Figure 2. The surface of Mars is dark at blue wavelengths and produces a good background for showing bright water ice clouds and north polar frost deposits seen in this image taken by the Hubble Space Telescope Wide Field and Planetary Camera 2 on 20 May, 1997. Features as small as 45 km can be seen. Ice clouds cover most of the Martian mid-latitudes and are especially prominent in the Tharsis Montes region to the left of the center of the planet. Four of the highest volcanic peaks can be seen poking though the clouds. The curved cloud contours in the upper left are suggestive of planetary-scale waves similar to those which drive large extratropical cyclones in the terrestrial atmosphere. (Photo courtesy of P. James, T. Clancy and S. Lee.)

cloud bands on the Earth. At night the surface can radiate to space efficiently and cool dramatically, leading to the formation of low-lying ground fog which dissipates soon after sunrise.

Although not classified as cloud, dust in the Martian atmosphere plays an important role in atmospheric dynamics and cloud formation. The Martian atmosphere usually contains enough dust to be a significant absorber of solar energy, heating the atmosphere during the day and promoting radiative cooling at night. Strong thermal contrasts at the edge of the polar frost deposit, coupled with the low density of the Martian atmosphere, can lead to high surface winds which pick up dust, sometimes progressing to a global dust storm that can blanket the planet, obscuring even the highest volcanos. After several months most of the dust sediments out and the atmosphere gradually returns to a cooler state more conducive to the formation of water ice clouds.

Venus

Venus and the Earth have similar size and mass but their atmospheres and cloud structures differ markedly (see VENUS: ATMOSPHERE). The Venus atmosphere is composed primarily of CO_2. It is massive (90 bars at the surface) and hot (740 K) near the surface. Because of its great fluid mass, slow rotation and greenhouse effect there is little horizontal thermal contrast (at most a few K from equator to pole) and consequently the dynamical regime is quite different than on the Earth or Mars.

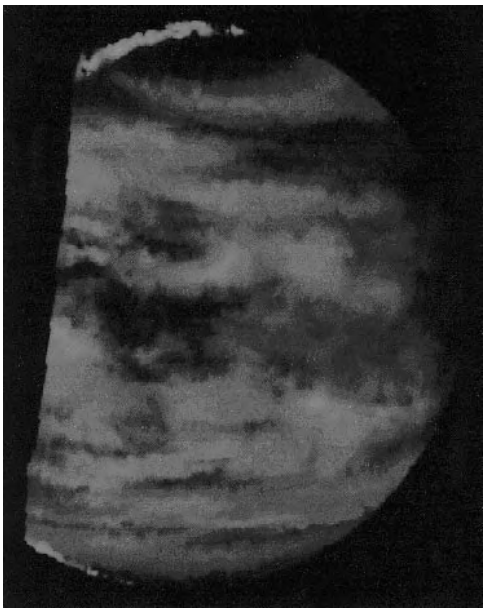

Figure 3. This image of the Venus nightside taken by the Galileo Near Infrared Mapping Spectrometer instrument at a wavelength of 2.3 microns in the near-infrared is bright where infrared light emitted by the hot surface is less attenuated by overlying clouds which block the radiation in the darker regions. The contrasts are produced mostly by variations in the number of large particles in the deepest of the three main cloud layers. These variations are due to atmospheric motions which are most vigorous in the lower cloud region.

Venus as seen through a telescope appears bright and almost featureless due to a ubiquitous thick layer of cloud. Subtle contrasts can be seen at violet and near-ultraviolet wavelengths. The material responsible for the contrast has not been identified with confidence but suggested candidates include elemental sulfur and the compound $FeCl_3$. Sulfur dioxide gas (SO_2) has been detected at the cloud tops, and the visible clouds are composed of liquid sulfuric acid (H_2SO_4) drops. At near-infrared wavelengths there are several spectral intervals (windows) where the gas opacity is relatively low, permitting infrared light radiated by the hot surface to penetrate the clouds. There is considerable cloud opacity even at those wavelengths however, so the contrasts seen in the near-infrared tell us mostly about the patchiness of the lower cloud layers which are more turbulent than the upper layer we see at visible wavelengths. These contrasts can be seen in figure 3.

Many spacecraft from the United States and the former Soviet Union have visited Venus. Several probes have descended into the atmosphere and measured pressure, temperature, gas composition, the internal radiation field and cloud particle number densities and sizes. The clouds extend over a very large vertical range. There are three main cloud layers at altitudes between about 45 and 70 km. Thin haze layers extend above and below those boundaries. Several experiments revealed the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

main cloud region to be composed of three layers. The top layer is concentrated between 59–66 km altitude. The middle layer lies between 49–57 km altitude and the lower layer is most dense in a 2 km region just below the 49 km boundary, at least as measured by the particle counter data on the Pioneer Venus large probe. Ground-based and Galileo near-infrared images (from the Near-Infrared Mapping Spectrometer—NIMS) later showed this layer to be highly variable in space and time (see figure 3).

The composition of the cloud particles is dominated by sulfuric acid, but some evidence suggests that an additional constituent may be responsible for the largest particles in the lower cloud layer. In the top cloud and haze sunlight breaks up SO_2 molecules which combine with water to form sulfuric acid with a concentration near 85% at the top, increasing at deeper levels. In the middle and lower clouds there is insufficient ultraviolet light to drive photochemistry and thermochemical processes become important in establishing chemical equilibrium. At the deepest levels the atmosphere and surface interact and the surface acts as a source and sink of sulfur and other constituents. The particle spectrometer on the Pioneer Venus large probe identified three sizes of particles. Mode 2 particles have radius close to 1 micron and dominate the top and middle clouds. Mode 1 particles are smaller (0.4 microns mean radius) and account for a few tenths of the optical depth in the upper cloud while mode 3 particles are larger (several microns or more) and provide much of the mass in the lower cloud.

The dynamical regime under which these clouds form is mostly stable in the upper two layers (altitudes above 49 km). These clouds are analogous to stratiform clouds in the terrestrial atmosphere. The subdued contrasts seen in the highest cloud move with the wind speed (about 100 m s^{-1}) at the visible cloud tops (near 70 km altitude) while the contrasts seen in the near-infrared window regions (e.g. figure 3) move at a slower rate (50 m s^{-1}, consistent with wind speeds measured by tracking entry probes). Estimates of the number of large particles in the lower cloud deck made by various entry probes varied by large factors. This observation supports the idea that the contrasts seen at near-infrared wavelengths are indicative of highly variable concentrations of large (several microns radius or larger) particles in the lower cloud deck. The lower cloud is a region of dynamical instability in the Venus atmosphere. The mechanism responsible for driving the Venus circulation remains unclear, although it seems likely that interactions between waves and the mean flow, initiated by absorption of sunlight in the cloud region, play a central role.

Titan

Like Venus, TITAN's atmosphere is a massive one with a dense haze layer and slow rotation and may be driven by the same mechanism. But the chemistry of the Titanian and Venusian atmospheres could hardly be more different. Titan's atmosphere is composed mainly of nitrogen with a few percent of methane and other hydrocarbons and nitriles (molecules with H, C, and N). Titan's atmosphere is cold (about 94 K near the surface and 71 K at the temperature minimum near 40 km altitude). At those temperatures methane may condense near the temperature minimum but some infrared measurements from the Voyager IRIS experiment suggest that a methane cloud may not be present. If that is the case methane would be supersaturated near the temperature minimum. Supersaturation does not occur in the terrestrial atmosphere (with respect to water) but can be achieved in the laboratory under controlled conditions. It will be difficult to resolve this issue until the Huygen's Probe descends into Titan's atmosphere in 2004.

Photolysis of methane in the high atmosphere leads to formation of ethane and other hydrocarbon and nitrile molecules. Processing of these molecules by long-term exposure to sunlight and charged-particle bombardment from space eventually produces a polymer haze which covers the satellite and blocks the surface from view at visible wavelengths. This haze is very dark at ultraviolet wavelengths and becomes bright, with little absorption at red wavelengths. It is composed of aggregates of small particles whose mean radius is close to 0.066 microns.

Chemical models predict a number of haze and cloud layers deeper in the atmosphere, composed of more volatile hydrocarbons. Methane is the most volatile and may condense below the temperature minimum (altitude range 10–40 km). A little higher in the atmosphere ethane may form a condensation cloud. Less volatile hydrocarbons and nitriles are expected to form condensate layers at higher altitudes, including C_2H_2, C_3H_4, C_3H_8, C_4H_2, HCN, C_2N_2, HC_3N, C_4N_2 and many heavier hydrocarbons. Carbon dioxide and water ice particles are also possible. Of these, only HC_3N and C_4N_2 particles have been detected spectroscopically. Detection of many of them is made difficult by Titan's obscuring photochemical haze at higher altitude. The spectral signature of C_4N_2 (dicyanoacetylene) ice was seen by the Voyager infrared spectrometer only in the polar haze of Titan. Analysis of these observations reveals that (1) ice particle mean radius is near 5 μm, and (2) the ratio of condensate to vapor mole fraction as inferred from the data is about 100 times more than expected from steady-state equilibrium of the constituents, accounting for creation of the vapor at high altitudes from photochemical production, and depletion of the vapor and condensate at low altitudes due to condensation and sedimentation of particles. The large disequilibrium ratio is probably a result of seasonal variation of photochemical destruction of vapor at high altitude and high latitude working in conjunction with a significant thermal time lag deeper in the atmosphere due to long thermal time constants.

There is almost no contrast on Titan at visible wavelengths apart from a hemispheric north/south reflectivity contrast which reverses over a several-year period as Titan responds to seasonal changes in insolation. There is a corresponding hemispheric difference in particle size in the upper haze which in turn is related to

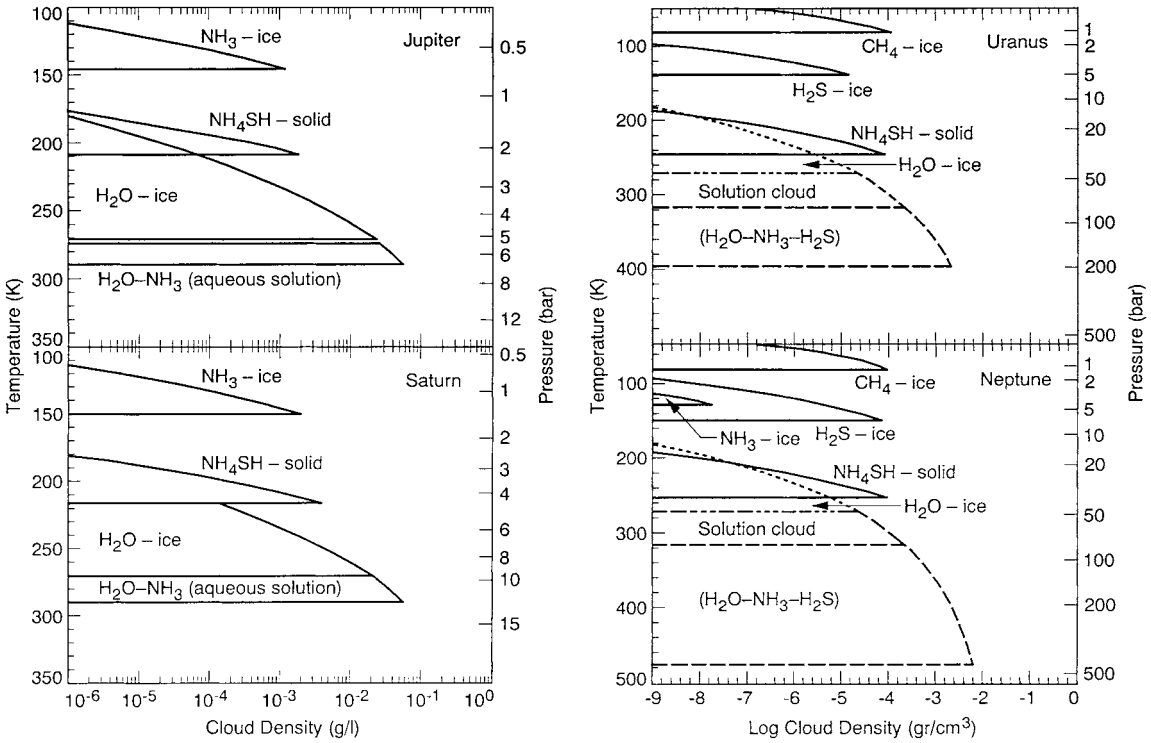

Figure 4. Thermochemical equilibrium models for the giant planet atmospheres indicate the vertical regions and compositions of ices expected to form clouds. Within these vertical regions actual cloud locations and densities are determined largely by atmospheric dynamics and microphysical processes. (Figures for Jupiter and Saturn were constructed from models by S K Atreya and M Wong, based on S K Atreya and P N Romani (1985) *Planetary Meteorology* ed G E Hunt (Cambridge: Cambridge University Press) pp 17–68. Those for Uranus and Neptune were first published by I de Pater *et al* (1991) *Icarus* **91** 220–233, © Academic Press.)

a hemispheric-scale rising and sinking motion which responds to seasonal change. Atmospheric aerosols contribute significantly to the heat balance in the stratosphere through their strong absorption of sunlight and therefore are important to the energy balance and circulation.

The giant planets

All of the giant planets Jupiter, Saturn, Uranus and Neptune have deep atmospheres composed mainly of hydrogen and helium with trace amounts of cloud-forming molecules water, ammonia (NH_3), ammonium hydrosulfide (NH_4SH), hydrogen sulfide (H_2S) and methane (CH_4). All of these except methane can condense in the atmospheres of Jupiter and Saturn. The atmospheres of Uranus and Neptune reach sufficiently cold temperatures near the temperature minimum at 0.1 b pressure to condense methane. Condensate clouds form in layers with the most volatile forming at higher altitudes where the temperatures are cooler.

Our ideas about composition are based on a combination of observations from the ground and spacecraft together with models of chemical reactions at the temperature and composition of the atmosphere. So far all of our measurements, except those from the Galileo probe which entered Jupiter's atmosphere (see GALILEO MISSION TO JUPITER), are made remotely with instruments from the Earth or on spacecraft (see JUPITER: ATMOSPHERE). The Galileo probe sampled a part of Jupiter's atmosphere that is thought to be depleted in condensable molecules, much like a desert region on the Earth, and so the probe measurements do not tell us about the global properties of clouds and cloud-forming constituents.

As a starting point in understanding the vertical locations and compositions of clouds we rely on thermochemical equilibrium models which make predictions from measured or inferred chemical abundance in the deep atmosphere, the pressure and temperature as measured by a variety of instruments, and knowledge of the chemical thermodynamics of the available molecules. This exercise can tell us at what altitudes to expect clouds and what their composition should be but it is not adequate for predicting the number densities of cloud particles at a given location because other processes such as atmospheric dynamics and cloud particle microphysics determine those quantities.

The cloud forming molecules mentioned above are observe to be or are predicted to be a factor of two or more abundant than they would be for a mix of solar atmosphere material at the same temperature and pressure. The

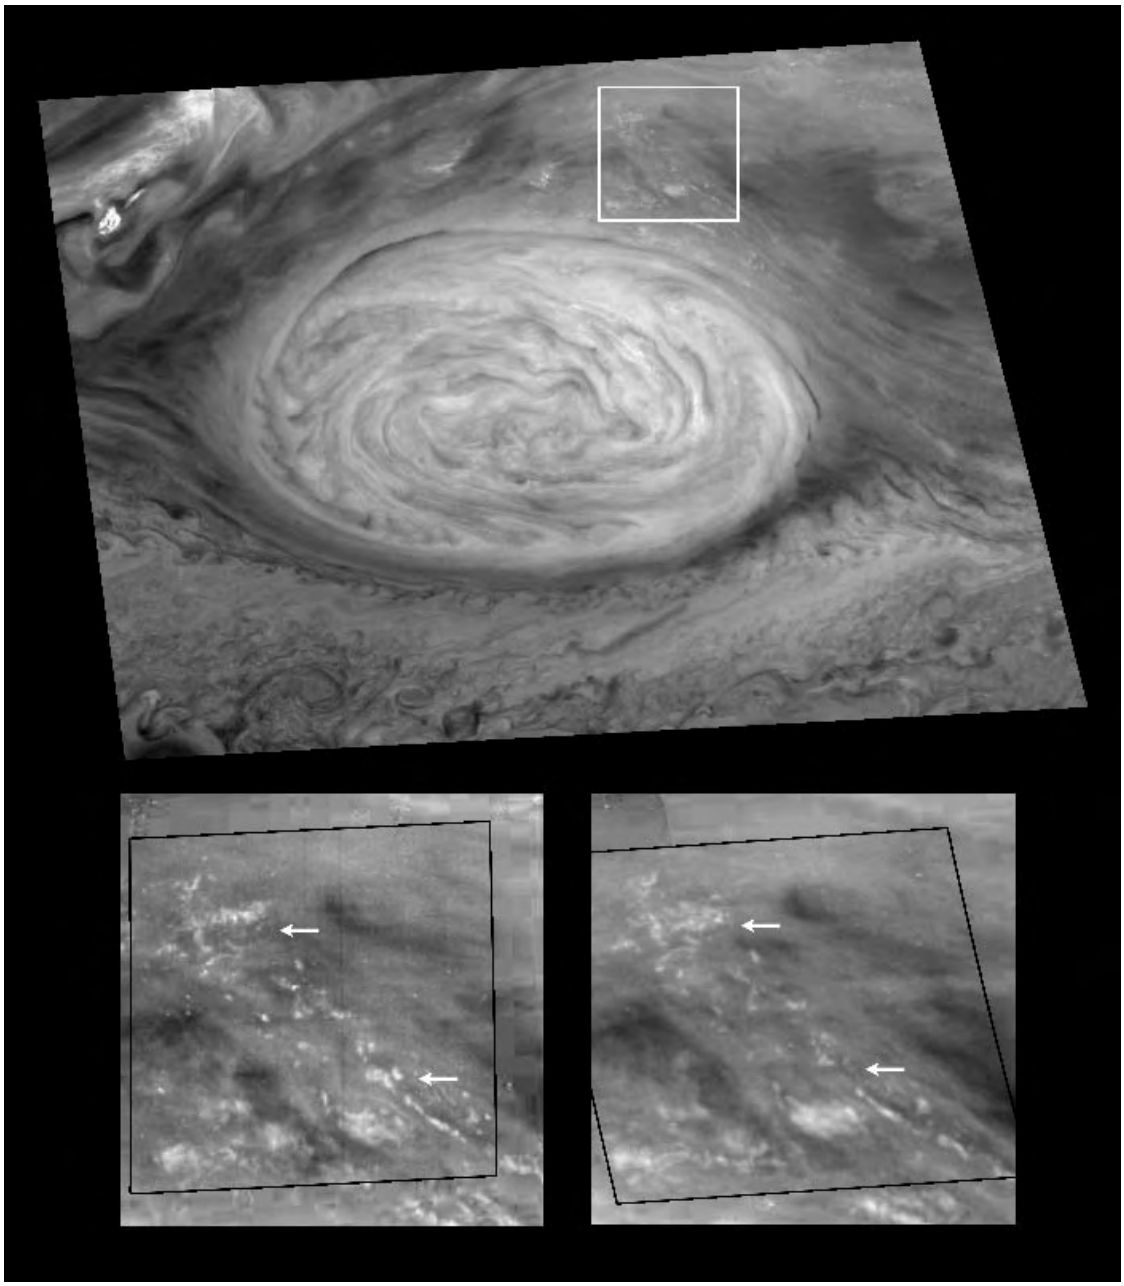

Figure 5. Jupiter's Great Red Spot and environs as seen by the Galileo Solid State Imager in 1996. The Great Red Spot centered in the top panel rotates counterclockwise. The embedded images shown in the two bottom panels reveal small puffy clouds about 50 km in diameter, possibly analogous to large terrestrial cumulus clouds. The time difference between the two bottom panels is 70 min.

enhancement of 'solar' abundance increases from Jupiter to Saturn to Uranus and Neptune, reflecting the fact that the larger planets were able to retain more of the light elements hydrogen and helium during their formation. An increase in the amount of available condensable molecule will result in cloud formation at a deeper level where the temperatures are warmer.

Predicted cloud locations for the four giant planets are shown in figure 4. JUPITER and SATURN form one pair with similar cloud types, while URANUS and NEPTUNE, which are colder, form a second. A water–ammonia solution cloud is predicted to form at pressure levels starting near 8 b in Jupiter's atmosphere and 15 b in Saturn's atmosphere. At higher altitudes (lower pressure and temperature) are clouds of ammonium hydrosulfide and ammonia ices. The topmost cloud in both cases is ammonia ice. A spectral

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

signature for ammonia ice was mysteriously not seen until recently in near-infrared spectra from the European Infrared Space Observatory (ISO) and the Galileo NIMS instrument. Spectral signatures of ices in the other clouds have not been observed. One of the Galileo Probe experiments detected particles near the 1.6 b level in Jupiter's atmosphere whose composition could be either ammonium hydrosulfide or water. It did not see a water cloud at the pressure levels where thermochemical equilibrium models predict, probably because water in the region it sampled is depleted due to a downwelling of dry air from the cold upper troposphere. It is not known how extensive a deep water cloud may be on any of the giant planets.

Uranus and Neptune are cold enough to condense methane which forms the top cloud in those atmospheres (see URANUS AND NEPTUNE: ATMOSPHERES, IONOSPHERES AND MAGNETOSPHERES). The next-deeper cloud, at a few bars pressure, is probably H_2S ice but may contain some ammonia as well. At deeper levels (10 to a few hundred bar pressure) are NH_4SH and water clouds.

The visibility of clouds varies markedly among the giant planets. Jupiter's atmosphere is filled with white-yellow clouds and darker yellow-brown clouds with a few regions that are more red (the GREAT RED SPOT) or gray (the hot-spot regions where upwelling infrared radiation at 5 microns wavelength can be seen). Jupiter's Great Red Spot is a large (about 3 times the size of the Earth) oval rotating in the anticyclonic sense (opposite to terrestrial storm systems). It has been observed for more than a century and probably owes its stability to the shear of the east–west zonal jets in which it is embedded. It is shown in figure 5.

All of the ices mentioned above are white at visible wavelengths. If these were the only cloud constituents Jupiter would appear as a featureless white ball. The colors and contrasts are due to a coloring material whose origin and composition is uncertain. Candidate materials include compounds of hydrogen bonded to sulfur, nitrogen and carbon (hydrocarbons) created by photolysis in the upper troposphere or by bombardment from high-energy charged particles precipitating from the magnetosphere. The latter process is almost certainly responsible for the formation of polar stratospheric hazes in the stratospheres of Jupiter and Saturn.

Cloud contrasts are subdued for Saturn and almost absent for Uranus. These planets as well as Neptune have deep cloud structures which reduce contrast and block upwelling thermal radiation. Contrasts are dominated by the jet structures, although there is not a one-to-one correspondence between cloud reflectivity and wind speed and direction. Saturn shows seasonal variations in cloud altitude. These result from solar heating of the upper atmosphere which influences the static stability and cloud altitude. These effects may well be occurring as well on Uranus and Neptune but seasonal changes for those planets occur on timescales long compared to our ability to observe them. Individual ovals and spots do form in the Saturn atmosphere. They can be seen most easily in contrast-enhanced images (figure 6).

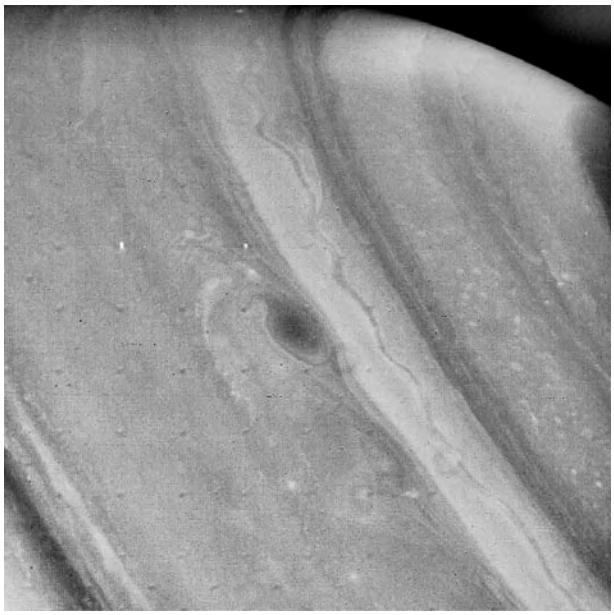

Figure 6. A dark oval and many smaller features can be seen embedded in the bright-dark cloud bands which line up with the jet streams in Saturn's atmosphere. A dark, kinked curve called the ribbon feature is centered in the bright band at 47° north latitude, the location of a high speed (150 m s^{-1}) jet. Cloud contrasts serve as markers of the wind and of the jet instabilities. This image was obtained by the Voyager 2 Imaging Subsystem in 1981.

The VOYAGER spacecraft viewed Uranus at a time when only one hemisphere was illuminated by the Sun. Only a few low-contrast cloud features were seen against an almost uniform thick cloud cover. More recently the near-infrared camera on the Hubble Space Telescope photographed a number of clouds in the opposite hemisphere (figure 7).

A number of cloud types were seen during the close Voyager flyby of Neptune in 1989. Several large ovals were seen. The largest of them was named the Great Dark Spot (figure 8). Like Jupiter, some coloring constituent of uncertain origin and composition is responsible for cloud contrast and color. These ovals move around and oscillate in longitude. The aspect ratio and tilt of the long and short axes of the ovals also oscillate. These oscillations can be understood with models that take into account the vorticity of the spot, its depth in the atmosphere, and the wind shear in which it is embedded.

Other types of clouds were seen in the Neptune atmosphere which are reminiscent of cirrus clouds and lee-wave clouds seen high in the terrestrial and Martian atmospheres. They are striated, they evolve rapidly with time (too rapidly to use as tracers of wind) and some of them form clumps that are tied to and overlay the larger ovals. The White Companion to the Great Dark Spot is the

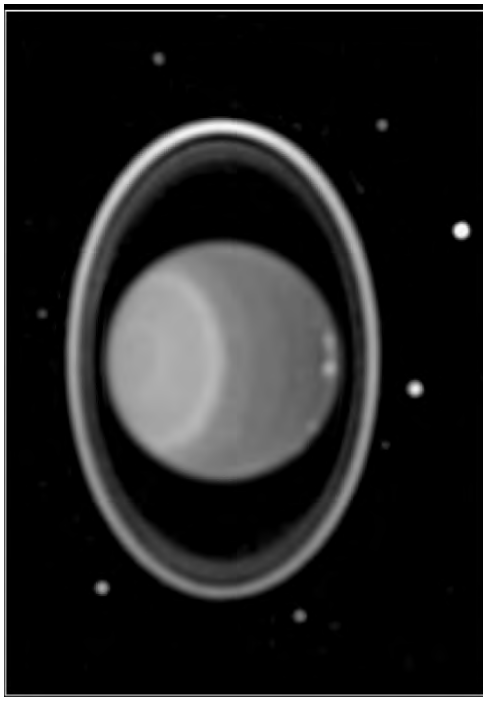

Figure 7. Near-infrared images obtained by the NICMOS camera on the Hubble Space Telescope provide the best views of clouds in the Uranus atmosphere. The entire planet is covered by clouds but the south polar region is covered by a relatively high, thick cloud layer and appears bright in this view. Small clouds, newly discovered in this image taken in 1997, appear in northern low latitudes, just above the terminator. The rings and 8 of the uranian satellites are also visible.

prime example of this. It was seen even in ground-based images in one of the methane absorption bands sensitive to high clouds. It can be seen in figure 8. These clouds are probably composed of methane ice, with the underlying thick cloud bank being H_2S ice.

Cloud microphysics

Cloud microphysics is the study of processes that govern cloud particle formation and evolution on the microscopic scale. It addresses such questions as 'What conditions are required for clouds to form? How rapidly do particles grow? What controls the particle size distribution?' The study of cloud microphysical processes goes beyond the microscopic. A broader goal is to understand the underlying processes which govern cloud structure and dynamics over large scales. A considerable amount of work has been invested in answering these questions for terrestrial clouds where *in situ* measurements can be made and coupled with laboratory and theoretical investigations. There has been some attempt to understand the microphysics of clouds on the other planets, although the observational constraints are much weaker.

Condensate particles can form either by direct condensation from supersaturated vapor or by condensing on a pre-existing foreign particle (dust or sulfate aerosol, for example). These are called homogeneous and heterogeneous nucleation, respectively. Homogeneous nucleation begins when molecules in the vapor phase combine to form a small cluster which can serve as a seed nucleus. The cluster molecules may evaporate, or more molecules from the vapor may condense, depending on which outcome is favored by thermodynamics.

The Gibbs free energy is the thermodynamic quantity which controls particle growth or evaporation. Gibbs free energy depends on two terms, particle surface area times surface tension plus particle volume times KT times the natural log of the vapor pressure divided by the saturation vapor pressure, or

$$\Delta G = 4\pi a^2\sigma - \tfrac{4}{3}\pi a^3 n_l K T \ln(e/e_l).$$

In the above equation ΔG is the change in Gibbs free energy associated with the formation of a particle of radius a, σ is the surface tension of the liquid, n_l is the number density of molecules in the liquid, K is the Boltzmann constant, e is the vapor pressure and e_l is the saturation vapor pressure at temperature T.

A plot of ΔG as a function of radius a reveals that the Gibbs free energy for particle formation is always positive for vapor pressure less than or equal to the saturation vapor pressure. This is thermodynamically unfavorable and any particle which may exist initially will evaporate. When the vapor pressure is higher than the saturation vapor pressure the Gibbs free energy becomes negative at some particle radius. There is a critical radius, a_c, where condensation onto the particle surface reduces the Gibbs free energy and the particle will grow by condensation.

Under normal circumstances in the terrestrial atmosphere it is extremely difficult to grow a particle up to the critical radius because the ratio of vapor pressure to saturation vapor pressure is never very high. A much more common initiation of the growth process depends on the existence of cloud condensation nucei (CCN) which may be composed of small dust or sulfate particles on Earth. A wide variety of CCN particle compositions may be present, but only a small fraction of them are conducive to growth. Particles whose surface structure is similar to that of water or ice (such as silver iodide crystals used for cloud seeding) make good CCN. Another class of particles which make even better CCN are hygroscopic sulfates and nitrates. An abundance of small CCN leads to an abundance of small droplets. Conversely, in an environment with few CCN, few water droplets will form, but the ones that do will take advantage of the available vapor to grow to relatively large size. Images of the ocean surface under some conditions reveal ship tracks as trails of small cloud particles whose formation was initiated by an abundance of CCN in the exhaust plumes of the ships.

Condensation alone is insufficient to grow particles in clouds to the point of precipitation over the coarse of a few hours. Another mechanism, growth by collision and merging of drops (coalescence) or sticking of ice

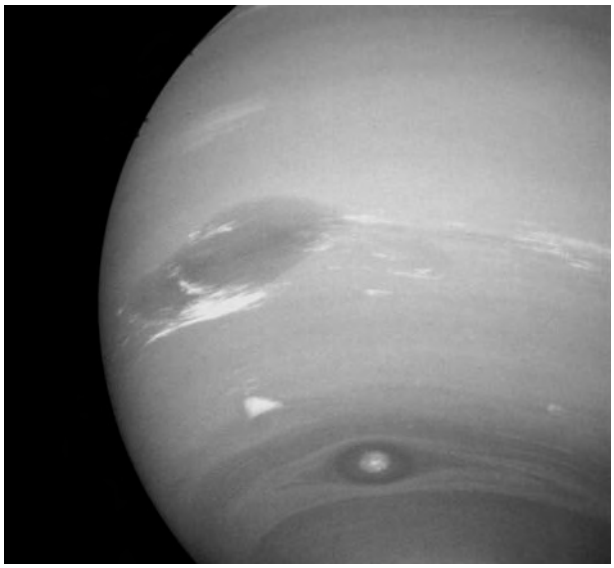

Figure 8. Neptune's Great Dark Spot (GDS) is the large dark oval to the left of center in this 1989 image by the Voyager Imaging Subsystem camera. The Bright Companion cloud forms at higher altitudes at the southern edge of the GDS. Several other bright clouds downstream (to the right) of the GDS and another large oval are also visible.

particles (coagulation), produces much more rapid growth when the particles become large enough (about 20 μm radius) that sedimentation velocities become important. The largest particles sediment faster than the smaller ones, and collide with other particles as they descend through the cloud. This behavior leads to a process which can rapidly grow large (up to about 2 mm) particles. Even larger particles can form in updrafts or parcels which cycle between updrafts and downdrafts.

These ideas introduce the interplay between cloud microphysics and vertical and horizontal winds. Another coupling is between radiation and clouds. At the top of the cloud layer the cloud cools by emitting thermal radiation to space. This cooling in turn feeds a circulation pattern with sinking cool air replaced by rising warmer air from below and within the cloud. Thus the three major physical processes (cloud microphysics, atmospheric dynamics, and radiation) are all coupled, and this coupling must be taken into account in cloud formation/evolution models.

Cirrus clouds form near the top of the troposphere where the temperatures are cold (some 40 °C lower than the freezing temperature of water). Clouds are supplied with vapor from the tops of large convective systems carried horizontally by the wind shear. Both liquid and ice can exist, with the liquid supercooled by more than 30 °C. Ice crystals can grow to relatively large sizes (on the order of 100 μm) as they descend. Ice crystals forming at a variety of temperatures produce a wide variety of crystal habits, but the dominant forms are hexagonal. Typical crystal angles are 120° and 90°. These lead to halo features, the most common at a scattering angle of 22°. Flat plates tend to orient in one direction as they fall due to their aerodynamical profile. Particle orientation leads to certain types of halos.

Microphysical models of Venus, Mars, Titan, and the giant planets

Venus

Our knowledge of the Venus cloud structure is considerable, thanks to extensive measurements from multiple instruments on several probes which descended though the atmosphere, as well as remote spacecraft and ground-based instruments. Models of the cloud microphysics must take into account the coupled chemical composition of the particles and gas (both change with altitude), photochemical processes at the top of the atmosphere, the temperature profile of the atmosphere, and vertical transport due to eddy motions and particle sedimentation.

Microphysical models attempt to reproduce the observed particle chemistry (sulfuric acid/water solution whose concentration varies with altitude as determined by temperature) and the size distribution and number density of the particles which also vary with altitude. Recalling that there are three principal cloud layers in the Venus atmosphere, the topmost is governed by photochemical processes which act on sulfur dioxide and water to produce a sulfuric acid cloud. The top cloud is close to steady state with little temporal variation. Particle growth matches loss by sedimentation. Particle growth is governed by the available sulfate produced by photochemistry. Sulfur dioxide is supplied by vertical transport from below the clouds. A bi-modal size distribution is observed in the top cloud with one mode having mode radius 0.3 μm, and the other with mode radius 1 μm.

The lower and middle clouds form by condensation from existing vapor rather than by photochemistry which drives particle formation in the top cloud. Two vapor constituents (H_2SO_4 and H_2O) are present in varying amounts. Small particles are present below the base of the lower cloud and these can serve as condensation nuclei. Model simulations show that the two most important parameters of the model are the vertical transport, as characterized by an eddy diffusion profile which is a function of altitude (it reaches a peak at 54 km altitude in the model), and the nucleation mechanism. The nucleation mechanism is thought to be a combination of heterogeneous nucleation on insoluble cores and an activation mechanism on soluble (hygroscopic) cores. A numerical model accounts for the balance in vapor pressures of H_2SO_4 and H_2O as a function of temperature, the supply of vapor via eddy diffusion, loss rates due to sedimentation, and continuity of particle mass as particles grow. The model reproduces the observed tri-modal particle size distribution. The smallest particles (less than 0.6 μm) are the insoluble cores. The largest particles (typically 3–4 μm radius) are those which nucleate near the top of the cloud. As they fall they grow by collision and condensation, becoming larger at lower altitudes.

Mars

Water molecules condense on dust nuclei in the Martian atmosphere to form water ice clouds. The water abundance is not high and so ice condensation requires both cold temperatures and availability of dust condensation nuclei. At very cold temperatures carbon dioxide can condense on the water ice particles.

Images from space and from the Viking and Mars Pathfinder landers have shown that ice cloud formation on Mars is highly variable. When Mars is farthest from the Sun the temperatures are colder and ice clouds are more extensive and more frequent. But even during the few weeks of the Mars Pathfinder mission cloud formation near the landing site was highly variable.

There are several major differences between ice cloud formation on Mars and the Earth. The water abundance in the Martian atmosphere is much less than that for Earth. As a consequence there are so few particles the coagulation process can be ignored, leaving nucleation, condensation and sedimentation as the factors which determine cloud formation and particle size distribution. The smallest particles are the same size as the condensation nuclei. The ability of Martian dust particles to serve as nucleation sites is highly uncertain because not much is known about the mineralogy, which has a strong effect on nucleation. Clay minerals might be present, and they typically are efficient nucleators. Other mineral types are inefficient. One way to account for the uncertainty in modeling this process is to make the contact parameter a parameter of the microphysical model. The energy associated with ice particle formation is proportional to the factor $(2+m)(1-m)^2$ where m is the contact parameter. Values of m close to 1 (e.g. for silver iodide, for example) reduce the energy of formation leading to rapid nucleation. Typical terrestrial soil particles have m near 0.4.

Microphysical models which employ the temperature profile as determined by the Mars Pathfinder instruments find ice cloud formation in two layers. The highest is in the altitude range 30–50 km. A second layer forms at the temperature minimum near 10 km altitude. Competition between growth by nucleation and condensation and loss by sedimentation defines the size distribution. Particles in the upper layer have mean radius near 1.5 μm, whereas those in the lower layer have mean radius near 2.5 μm.

Titan

As is the case for the Earth, Venus, and the giant planets, clouds or haze in the stratosphere form as a result of photochemical processes, whereas those in the troposphere form from condensation. At the deepest level there should be methane clouds. Other condensate clouds, possibly with a variety of compositions, may form at intermediate levels.

Methane cloud formation near the temperature minimum (below 40 km altitude) is highly uncertain. The Voyager infrared spectra have been interpreted by some to imply that methane is highly supersaturated near the temperature minimum. This cannot occur in the presence of a substantial cloud, and so would imply that condensation occurs only rarely, forming large ice (or liquid in the lowest few km) particles which fall rapidly to the surface (rain without clouds). That scenario was proposed prior to the interpretation of high global supersaturation of methane. Titan and the Earth may differ significantly in terms of the number of condensation nuclei available to initiate particle formation. On the Earth there are numerous CCN mixed up from the surface. On Titan the only CCN available may come from slow sedimentation of the overlying photochemical haze and from other condensates. The number density from that source is thought to be quite low compared to that for the Earth. Low CCN density would lead to fewer particles, but those that form can grow by condensation to large size (radii greater than 50 μm) because their formation does little to deplete the available vapor. Both microphysical models and recent ground-based near-infrared spectra imply patchy and variable clouds of large methane ice or liquid particles which form at an altitude near 15 km.

Titan's stratospheric photochemical haze is composed of complex hydrocarbons and nitriles. The starting point for this process is the photolysis of methane and nitrogen high in the atmosphere (higher than 300 km altitude). Although the process is slow, over geologic time enough methane should have been processed to generate 100 m thick surface deposits of liquid ethane and solid organic material, provided a surface reservoir of methane has been available to replenish that which is destroyed over billions of years. The haze particles are undoubtedly complex organics and nitriles, although not enough is know to be more specific regarding the composition.

Microphysical models for Titan's stratospheric haze lump the chemical processes leading to formation of condensable organics into one adjustable parameter, the mass production rate of aerosol-forming molecules at the top of the haze layer. Nucleation is assumed to be initiated by formation of small clusters of molecules which grow through collisions. Models include particle charging by UV and cosmic ray events. Charge is a free parameter (number of electrons per unit particle radius) and serves to inhibit growth by coagulation. Traditional microphysical models assumed the particles remain spherical as they grow. This would be expected if the particles are liquid. More recent models incorporate laboratory results and theoretical predictions which favor solid particles. As solid particles collide they stick together to form aggregates. As the aggregates collide with each other they form larger aggregates which have a fractal nature. Cluster–cluster aggregates have fractal dimension close to 2 (versus spheres which have fractal dimension 3). Near the top of the haze layer ($\sim$400 km) the growth process is via molecules which stick to individual particles. The individual particles grow to some size limit determined by the pressure. Both theory and observation indicate the individual particles, or monomers have radii near 0.066 μm. Mutual collisions among the monomers give rise to clusters and to cluster–cluster aggregates as the

Dirac House, Temple Back, Bristol, BS1 6BE, UK

particles settle. The cluster aggregate idea can explain the combination of strong linear polarization in light scattered near 90° scattering angle and the strong scattering of light in the forward direction.

Giant planets

Microphysical studies of the condensate clouds in the tropospheres of the giant planets rely on the familiar principles which describe growth by condensation, coagulation, and coalescence and loss by evaporation and sedimentation. However, these models are extremely crude because the number and composition of potential cloud condensation nuclei are unknown. Furthermore cloud formation depends strongly on atmospheric dynamics which are not taken into account. There are no *in situ* measurements except for the Galileo probe which found few particles in its descent path through a volatile-depleted patch of Jovian atmosphere. Some microphysical models predict that the methane clouds on Uranus and Neptune are 10–100 times more massive than any clouds on Earth. However, the observations show very little methane cloud mass. Observational evidence for the water cloud is lacking, although higher clouds interfere. The ammonia cloud near the top of the troposphere on Jupiter and Saturn is predicted from microphysical models to be a weakly precipitating cloud similar to terrestrial cirrus, and observations are consistent with that idea.

Coupled photochemical/cloud microphysical models are able to account for the optical depth and size distribution of hydrocarbon haze particles in the stratospheres of Uranus and Neptune, provided the mass production rate and particle charge are adjustable parameters. The models account for particle sizes (all submicron) and vertical profiles as derived from Voyager data. Eddy diffusion transports methane to the upper atmosphere where photochemical processes lead to formation of diacetylene, acetylene, and ethane ice particles which condense near 0.1 mb, 2.5 mb, and 14 mb, respectively. As the particles fall to pressures greater than 600 mb they evaporate as the temperature rises. Organic polymers can also form, probably via solid-state photochemistry within the original ice particle during the settling lifetime. This process can account for the weak absorption seen in reflected sunlight.

Clown Face Nebula (NGC 2392)

A planetary nebula, also known as the Eskimo Nebula, in the constellation Gemini, position RA $07^{h}\ 29.2^{m}$, dec. $+20^{\circ}\ 55'$. It is bluish, $13''$ in diameter, and of ninth magnitude, with a tenth-magnitude central star. The blue-green nebula's hazy outer regions are thought to resemble an Eskimo's hood or clown's ruff.

Cluster

Two European Space Agency missions to send four identical spacecraft to explore the interaction between Earth's magnetosphere and the solar wind. SOHO and Cluster made up the first ESA 'Cornerstone'. Cluster I was lost in the failed maiden launch of the Ariane 5 rocket in 1996. Cluster II, which replicates the original mission, will be launched from Baikonur in summer 2000. Four spacecraft will provide the first three-dimensional measurements of large- and small-scale phenomena in the near-Earth environment.

Cluster Membership

Our Milky Way Galaxy contains numerous stellar systems, the members of which are thought to have a common origin and are gravitationally bound. The galactic GLOBULAR and GALACTIC OPEN CLUSTERS are the most important representatives of such systems. Less conspicuous are the low-density and gravitationally unbound stellar associations. There is a tight link between the open clusters, associations and the galactic disk which is readily visible on the starry sky. However, the galactic disk is very rich in stars, such that the open clusters and associations, projected against this background, start to blend with it. This blending, or in other words the cluster contamination by galactic disk stars, becomes severe at fainter magnitudes. Handling the cluster contamination is pretty much part of the problem of determination of cluster membership. The galactic globular clusters, on the other hand, are so rich in stars that a casual background star rarely is adopted as a cluster member. This may not be the case if the globular cluster is poorly populated and/or is located near the center of the Galaxy where the background star density reaches a maximum.

Why do we need to identify the cluster members as confidently as possible? Observation of STAR CLUSTERS is important for comparison of the theories of STELLAR EVOLUTION and STELLAR FORMATION with observations. In fact, the stellar evolution theory for stars younger than a few Gyr almost entirely rests on observations of open star clusters and the Sun. If the observations of a star cluster are contaminated by background stars, it inevitably will affect the cluster's HERTZSPRUNG–RUSSELL (HR) DIAGRAM and the derived mean properties of the cluster may be in error. In turn, stellar formation theory requires knowledge of the stellar initial mass function (IMF), which in principle can be deduced from the observations of star clusters. Again, the contamination together with completeness of cluster membership are the crucial issues in an attempt to derive the IMF.

A prerequisite to a thorough study of any specific star cluster and association is a membership determination, which is valuable in its own right. Membership determination presents a paradoxical situation. On the one hand the concept is easy to grasp but on the other hand, the practical implementation has kept generations of astronomers busy and surely will in the future. This paradox is sometimes overlooked even by workers in the field and is not adequately acknowledged by others using cluster-study results.

The following discussion has a passing connection to the group of statistical methods known as clustering techniques, which are often used in the analysis of galaxy distributions. In the case of star clusters, the underlying assumption is that their existence usually is well established, whereas individual membership probabilities may not be known.

Membership probability

Since the star clusters are projected onto the Galactic star field, we always deal with a mix of two populations: the cluster (c) stars and field (f) stars. There is no readily available criterion which will give us a clear discrimination between these two populations. Thus, we can only estimate a star's probability, p, of being a member of the cluster, which can be defined as follows:

$$p = \frac{F_c}{F_c + F_f} \tag{1}$$

where F_c and F_f are some distribution functions (often called the probability density functions, pdf) for the cluster and field respectively. These functions, in turn, are dependent on some physical quantities and their errors characterizing the cluster and field stars.

In principle, any membership criterion based upon physical or other phenomena is useful, as long as it allows one to separate the cluster and field population to some degree. A true cluster star will probably pass all 'filters' set by different approaches if the assumptions are correct and unbiased, whereas a field star is expected to fail on at least one of them.

Usually, star clusters have been discovered as local, projected star-density enhancements on the sky. As a first cut, one can draw an imaginary circle on the sky around such enhancement and declare that every star within the circle is a cluster member. Unfortunately, at fainter magnitudes this approach leads to poor results. As an example, let us consider the case of a relatively nearby open cluster, Messier 39. Armed with *a priori* knowledge of true cluster members, it is possible to estimate the mean probability for each star to be a cluster member at different apparent magnitudes within a radius equal to 15 arcmin around the cluster center. In table 1 a cluster membership probability of 75% means that 3/4 of those stars are cluster members, whereas 1/4 are field stars. Since this is a probability, we cannot tell which specific stars are the cluster members. Obviously, the lower the probability, the lower the chances of finding a cluster star in the sample.

As seen from table 1, down to V ~11 mag the number of cluster stars is high enough to let us ignore the presence of field stars. However, at fainter magnitudes the cluster members virtually vanish into a sea of field stars. This is a very common picture in open cluster studies.

Fortunately, there are a few features which are different for stars in clusters and those in the galactic field. For example, due to their common origin and

14	2	30

gravitational field the cluster stars are located within a limited volume rarely exceeding 20 pc in diameter. In the HR or the color–magnitude diagrams cluster stars are mainly located within a narrow band along the main sequence, with the exception of very young open clusters in which the less massive stars are scattered well above the so-called zero-age main sequence. On the other hand, the distribution of galactic field stars in the color–magnitude diagram merely forms a wide and diffuse cloud. This difference in appearance of color–magnitude diagrams is one frequently used method to delineate the cluster stars from the field. Although it never deals with calculation of membership probabilities, in essence it boosts membership probabilities *en masse*. However, moving down to fainter magnitudes, there always is a critical region of the color–magnitude diagram where field stars pollute the diagram beyond recognition. Ironically, at the moment this region occupied by the faintest members of star clusters, such as white and brown dwarfs is at the center of attention of many astronomers for very good reasons. These objects can provide an independent absolute age scale and may reveal some secrets of planet formation. Apparently, there is a need to derive real cluster membership probabilities, not just estimates.

Any star's motion can be divided into two measurable quantities—tangential velocity on the sky or the so-called proper motion, and radial velocity along the line of sight. These two velocities are heavily used in calculating the membership probabilities and certainly warrant a closer look.

For a typical open cluster, the scatter of field-star motions is approximately up to a hundred times higher than the dispersion of internal motion velocities around the cluster center of mass. Essentially, this disparity is the key in determination of cluster membership using star motions. Of course, each cluster has its own systemic motion within the Milky Way. Membership determination is much easier if this motion is significantly different from the mean motion of field stars.

Proper motion as a tool for membership

Although the existence of PROPER MOTION has been known since its discovery by Edmond Halley in 1718, it is not easy to measure a star's proper motion.

First, proper motions are very small. A typical unit for measuring the proper motion is a milliarcsecond per year (mas yr^{-1}) and very few stars have motions exceeding 1000 mas yr^{-1}. In the cluster world, the Hyades cluster members possess the largest proper motion, around 100 mas yr^{-1}. Second, the standard ground-based technique for determination of proper motion requires a concerted long-term observational effort. Traditionally, the positions of stars are measured on two or more sets of photographic plates taken at different epochs spanning at least several decades. Then, all measured coordinates are reduced into a common coordinate system at a fixed epoch, allowing a linear time-dependent coordinate term for each star (a.k.a. proper motion) in addition to the conventional global polynomial terms. The reliability of a proper motion is characterized by the ratio of the proper motion to its standard error. The rule of thumb is, the longer the time span, the more precise the proper motion. It is relatively easy to obtain proper motions at the 1 mas yr^{-1} accuracy level, although sub-mas yr^{-1} accuracies are still a challenge. Moreover, for most of the open clusters there is virtually no early plate material available, and when it is, the plates frequently do not contain faint enough stars.

The importance of proper motion in cluster membership determination was understood long ago, but a thorough exploitation of proper motion started only with the introduction of photography in astronomical observations during the last decades of the nineteenth century. Since then, about 100 out of 1200 known open clusters have at least one determination of proper motion using the photographic method, as opposed to about 500 clusters having had photometric observations accomplished.

A special place in cluster membership studies is occupied by the recent very successful HIPPARCOS mission and planned future space astrometry missions, such as SIM, FAME and GAIA. Hipparcos has made a significant impact on the nearby open cluster and association membership and census. Due to expected positional accuracies at the unprecedented micro-arc-second level, the future space missions, FAME and GAIA, will be in a position to provide excellent membership information for virtually all registered open clusters. These future missions are expected to revolutionize studies of the Milky Way, including the star clusters.

As said before, membership determination using proper motion utilizes the fact of quite different dispersions in the velocities of cluster and field stars. In practise, however, each determination of proper motion has some error. In other words, the true proper motion is

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

always somewhat blurred due to measuring and other errors. If these errors are comparable with the dispersion of field stars (usually around 5–10 mas yr^{-1}) and systemic motion of a cluster does not differ significantly from the mean motion of field stars, then cluster member segregation is impossible.

Consider again the open cluster Messier 39, which has a rather large sample of stars having proper motions with accuracies slightly above 1 mas yr^{-1}. The working tool to analyse proper motion is the so-called vector-point diagram (VPD). In this diagram (figure 1) with axes usually oriented along right ascension and declination, each dot is the end of a proper motion vector. Two populations of dots can be noticed: a large concentration around (0,0) and a smaller one around (–6, –16) mas yr<figref id="EAA2854fig1">. The latter essentially represents the cluster stars. Since errors are the major source of cluster-star dispersion in VPDs, the distribution of cluster stars is very close to Gaussian. The dispersion of field stars is mainly caused by true motion of the galactic stars which, generally speaking, do not obey any simple distribution; however, superposition of many smaller distributions of a poorly known nature produces a distribution which appears Gaussian. This fact is used by astronomers to calculate the membership probabilities just from proper motions in the following manner. The cluster and field proper motion distribution functions, F_c and F_f, are expressed explicitly as two separate Gaussians with their own parameters. The sum of these distributions, $F_c + F_f$, essentially represents the distribution of vector points in the VPD. A number of mathematical techniques are devised to find the parameters of these distributions. Once they are known, it is trivial to calculate individual membership probabilities using equation (1). The second set of mean probabilities in table 1 shows how dramatically the mean membership probability increases at fainter magnitudes with respect to the would-be probabilities of a smaller central star sample. Despite the area of the sky under the survey being more than ten time larger, the proper-motion-based probabilities still are very reliable, and what is more important, such probability is provided for each star in the sample. These probabilities are totally independent of any astrophysical theory predictions, for instance how the cluster color–magnitude diagram should look. This provision is critical in the case of 'weird' stars, such as blue stragglers, variables, binaries and other exotic objects. Figure 2 shows the color–magnitude diagram for all stars in the region of Messier 39 (figure 2(*a*)). The cluster's upper main sequence is barely visible; however, with the help of proper motion virtually all field stars are gone (figure 2(*b*)) and the main sequence is beautifully delineated.

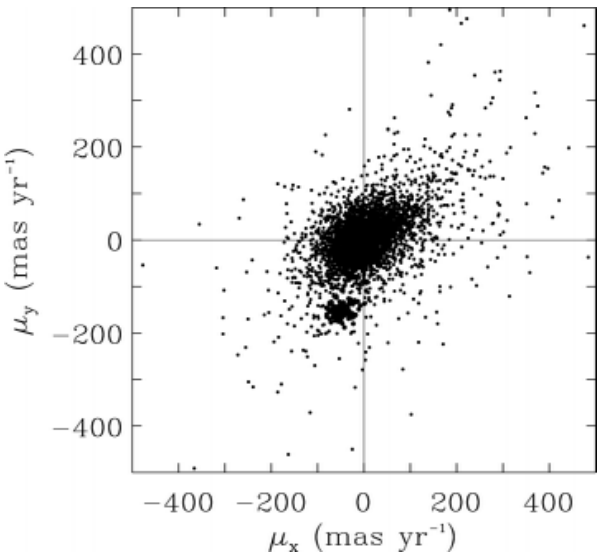

Figure 1. Vector-point diagram of proper motions in the region of open cluster Messier 39. Each dot is the end of a star's proper-motion vector originating from the zero point. The cluster stars can be recognized as a small clump around (–6, –16) mas yr^{-1}.

On the other hand, proper motion is not an absolute criterion in deciding the membership of a single star of particular interest. Even a high membership probability, by the very nature of probabilities, leaves a chance for a field star. Thus, if possible, another criterion, such as radial velocity, should be used.

Radial velocities

RADIAL VELOCITY determinations are made by measuring the Doppler shift in the spectra of stars, i.e. the displacement of spectral lines, $\Delta\lambda$, with respect to their wavelength at rest, λ_0, as determined from laboratory measurements. In the classical framework this displacement is proportional to the velocity along the line of sight

$$v_r = c\frac{\Delta\lambda}{\lambda_0} \qquad (2)$$

where c is speed of light. The radial velocities of open cluster stars, as measured from the solar system, rarely exceed 10–20 km s^{-1}, hence a required accuracy of radial velocities to ±1 km s^{-1} or better necessitates that the wavelength displacement must be determined to a few parts in a million, which is a challenge even to modern spectroscopy. The most frequently used technique for radial velocity measurements is the cross-correlation of an observed spectrum with a high-quality template (optical or synthetic) of a reference spectrum. This way it can be done directly, while observing as in the CORAVEL spectrometer, or numerically, using the CCD spectrograms taken for one star at a time as in the

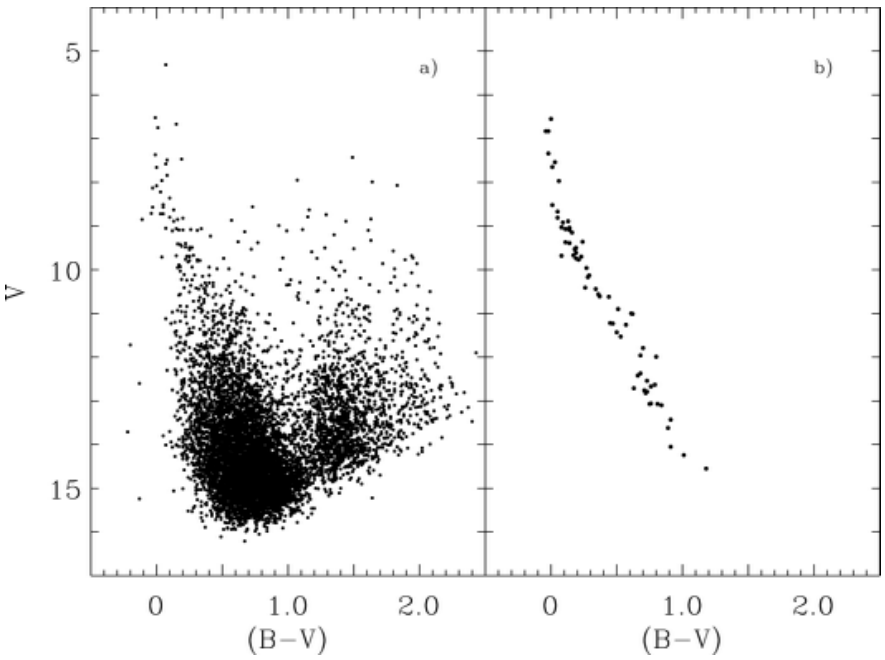

Figure 2. Color–magnitude diagram in the region of open cluster Messier 39: (*a*) all stars; (*b*) only probable cluster members.

French/Swiss ELODIE and CORALIE designs and digital speedometers developed at the Harvard-Smithsonian Center for Astrophysics, USA, or for many stars simultaneously (cf the Hydra multi-object spectrograph on the WIYN telescope at Kitt Peak, USA). The most accurate radial velocities have been achieved by placing an absorption cell (HF or iodine) in front of the spectrograph, but this technique requires a high level of light flux and is mainly used in extra-solar planet hunting around bright stars.

The spectra of late-type (F-G-K) stars contain a large number of small-width metal absorption lines which makes the application of cross-correlation techniques relatively easy. This explains why the vast majority of cluster stars having precise radial velocities are of late spectral type. Due to the scarcity of spectral features coupled with their strong dependence upon the physical conditions in STELLAR ATMOSPHERES, and often large rotational velocities of hot stars, it is much more difficult to measure radial velocities of early-type O, B and A stars which usually are the brightest in open clusters. Recent advances in modelling the stellar atmospheres and tuning these models to a star's actual physical parameters promise to close this gap soon.

Figure 3 shows the distribution of radial velocities in the open cluster NGC 188. In some sense it resembles the vector-point diagram, though just in one coordinate. In principle, it is possible to model the cluster and field star distributions, but for two stumbling blocks. First, the radial velocity measurements are telescope-time prohibitive and, hence, the star samples are always optimized to include a maximum number of potential cluster members. In other words, such selection is greatly biased towards cluster members. This causes a severe under-representation of field stars and, consequently, undermines the statistical grounds for calculating the membership probabilities. Secondly, about half or even more of cluster members can be binaries (some are even triple systems), like those marked in grey in figure 3. The orbital motion will induce a time-dependent offset relative to the mean motion of the binary system. To detect such an offset motion, the observations must span a considerable part of the orbital period. If the offset goes undetected, then a star could be erroneously categorized as a field star. While this may appear annoying for the determination of cluster membership, most researchers thrive on binaries, since they provide such fundamental astronomical data as masses, radii and luminosities, and have a profound impact on star formation history and dynamical evolution of stellar systems (see also BINARY STARS IN GLOBULAR CLUSTERS).

For these reasons, the determination of cluster membership from radial velocities is so far limited to a simple division of stars into cluster members and non-members, depending whether or not their radial velocities fall within the 3σ window around the cluster's mean radial velocity. Nevertheless, even such a rudimentary membership in combination with a membership from proper motions weeds out field stars quite effectively. To date, about 200 open clusters have some sort of radial velocity measurements, mainly for the giant-branch stars. Only a dozen of them, mainly the nearby clusters, have measurements for the main-sequence stars, but this is

rapidly improving with new advances in the multi-object spectrograph design and the availability of large telescopes.

Membership in associations

The stellar association membership presents a real challenge to anyone attempting to determine them. Most common are the so-called OB ASSOCIATIONS. These associations are gravitationally unbound star systems, recognizable by some excess density of O and B spectral type stars against the sky background and a small internal velocity dispersion. The latter does not exceed a few km s^{-1} and, as a result, the association can be detected by common kinematics of its members, though in a less consistent manner than for the star clusters. Since the associations cover tens to hundreds of square degrees on the sky at extremely low density (a few stars per square degree), before the Hipparcos mission the membership information was limited to the bright stars and even it was not reliable. The Hipparcos measurements are ideally suited for membership determination in nearby OB associations out to the distance of ≈650 pc.

The large spatial extent of associations prompts researchers to use the so-called moving cluster technique. All association stars are moving so that a receding association approaches a location on the sky known as the covergence point. In the case of associations this is only partially true because the star motions are slightly diverging. Apparently, the velocity dispersion perpendicular to the direction of the association's motion is just a combination of an intrinsic velocity dispersion convolved with the observational errors. The distribution of this velocity dispersion is used to calculate membership probabilities for associations. With the advent of Hipparcos parallaxes and proper motions it is possible to derive an elliptical membership probability cylinder in 3D velocity space, which constitutes the so-called 'spaghetti' method introduced by Dutch astronomers. Now a much better census of the stellar content in stellar associations is known to within 1 kpc of the Sun.

Globular clusters

The main thrust in globular cluster astrometry is towards the determination of absolute proper motions which allow one to calculate the orbits. The knowledge of orbits is crucial in understanding the content and properties of presumably a rather heterogeneous system of globular clusters, some possibly captured during galactic merger events (see GLOBULAR CLUSTER SYSTEMS IN INTERACTING GALAXIES).

High-precision relative proper motions are required to identify potential field stars projecting onto the cluster. Thus, the Yerkes refractor plate material has produced clean samples of cluster stars in a dozen globular clusters. Since the globular clusters are rather distant objects, only upper parts of the cluster color–magnitude diagram are visible on old photographic plates. It is expected that the Hubble Space Telescope (HST) archival CCD frames will be useful in producing deep membership studies in globular clusters. The positional accuracy on the HST CCD frames is sufficiently high to reach a sub-mas yr^{-1} accuracy level for proper motions in a few years, a feat impossible from ground-based observations.

Embedded clusters

This is a class of very young open clusters surrounded by thick clouds of molecular gas and dust, presumably leftovers from star formation. Usually these clouds block out most of the star light. However, in the near-infrared wavelengths the clouds become fairly transparent. With the advent of panoramic near-infrared wavelength detectors it is possible to sample the nearby ($d < 1$ kpc) embedded clusters down to and well below the hydrogen burning limit. Such clusters are ideal places to study the stellar initial mass function (IMF), since stellar evolution and dynamical effects have minimally changed the content and mass of embedded clusters. On the other hand, even at infrared wavelengths the extinction in the direction of cluster members can be non-uniform, which coupled with the emission due to the presence of circumstellar disks and other remnants of star formation make the mass determination rather difficult.

For the handful of well-studied embedded clusters, cluster membership is still not available for a couple of reasons. First of all, the density of stars in these clusters is much higher than in the surrounding field, thus allowing one to apply a simple statistical field-star subtraction. Secondly, the time span between the first and second epoch imaging-array frames is currently too short to derive reliable proper motions. In addition, the whole field of INFRARED ASTRONOMY is rapidly evolving and the future instrumentation will most likely provide new means to find the cluster membership.

Alternative membership method

The faint end of cluster sequences in the HR diagram is invariably contaminated by field stars due to a couple of aggravating circumstances. First, the cluster luminosity function (in essence, the number of stars per unit magnitude) at around the solar luminosity and fainter is getting flat, mainly due to the effect of dynamical 'evaporation' of cluster stars. On the other hand, the field-star luminosity function is steadily growing. In this situation, the observed ratio of cluster to field stars is plummeting and so are the membership probabilities. Second, at faint magnitudes membership is plainly lacking because of the shallow old-plate limiting magnitude and unacceptably low light-flux levels for radial velocity measurements.

It turns out that the majority of young stars of spectral type A and later have considerable coronal activity, showing up in x-rays. The ROSAT x-ray satellite, operating from 1990–8, was the prime instrument to map out the 'soft' (0.1–2.4 KeV) x-ray sky. It was quickly realized that almost all nearby clusters of Pleiades age and younger should be visible on the ROSAT x-ray 'sky', and these positive identifications can be used as a valuable membership criterion. Using the ROSAT data, nearly a dozen open clusters have their membership lists enlarged substantially at the faint end. Although, it is not entirely clear if all fainter cluster stars have such x-ray activity, it is nevertheless a powerful alternative membership determination technique to complement classical kinematical methods. Perhaps its potential somewhat diminishes in the areas of nearby OB associations where the fraction of x-ray bright field stars is higher.

Future

Despite the huge effort put into the determination of star cluster and association membership, there is still plenty of work ahead. Not a single cluster is known, for which we have discerned all cluster members. To make matters more complicated, the Hipparcos observations have revealed a number of cluster stars beyond the tidal radius for the nearest open clusters. The tidal radius is the distance beyond which the cluster loses its stars due to Galactic gravitational tidal forces. This means that the all-sky proper motion and parallax surveys, such as the planned GAIA mission, should be used to derive a decisive and complete cluster or association membership. The parallax will provide a hitherto missing positional coordinate—the distance. The cluster membership can be rigorously derived only with a full bundle of three positional coordinates and three velocity components in hand, which, compared with the potential energy of a cluster, ultimately defines whether or not the star is likely to be bound to a cluster. The instantaneous positional accuracy of the planned astrometric missions is so high that it would take only a couple of months to achieve the best ground-based proper motion accuracy, as opposed to the several decades needed before.

Cluster of Galaxies

A collection of galaxies that is held together by gravity. Clusters may contain from a few to a few thousand member galaxies. Small clusters, with up to a few dozen members, are referred to as 'groups', the Milky Way Galaxy, for example, being a member of the Local Group, which contains at least 25 members. Most galaxies are members of groups or binary pairs. Larger clusters contain hundreds or thousands of members and, typically, have diameters of a few megaparsecs (about 10 million light-years). Rich (densely populated) clusters are divided into regular clusters and irregular clusters.

Regular and great regular clusters are fairly symmetrical spherical systems with a strong concentration of galaxies towards their centers. They frequently contain several thousand members, the great majority of which are elliptical or lenticular (S0) galaxies, and usually contain one or more giant elliptical (cD) galaxies at their centers. It is believed that numerous collisions and mergers have taken place in clusters of this kind, and that giant galaxies have grown by absorbing smaller ones, a process that is sometimes called 'galactic cannibalism'. The shortage or absence of gas-rich spirals within such clusters is believed to be the result of gas being stripped out of them, or converted rapidly into stars, during collisions and close encounters. Such clusters often contain substantial quantities of tenuous high-temperature gas (with temperatures of the order of 10^8 K), which radiates at x-ray wavelengths. Irregular clusters are more diffuse and less structured. They contain a mixture of all types of galaxy, including substantial numbers of spiral galaxies. Within clusters of this kind, close encounters and collisions are relatively rare.

The nearest large cluster is the Virgo cluster, an irregular aggregation of more than a thousand galaxies that lies at a distance of about 50 million light-years. The nearest rich regular cluster is the Coma cluster, which lies at a distance of about 300 million light-years, and is estimated to contain up to ten thousand galaxies.

Studies of the internal dynamics of clusters (the speeds at which the member galaxies move around within the cluster) imply that most clusters can hold themselves together by gravitational forces only if they contain at least ten (and in some cases up to a hundred) times as much dark matter as luminous matter.

Collimation

The process whereby the components of an optical system, such as a telescope, are positioned and aligned to give optimum performance. For a refractor, each lens should be centered on, and perpendicular to, the optical axis of the telescope. Cassegrain reflectors, and related types, are collimated by ensuring that the axis of the primary mirror passes through the center of the secondary mirror and that the centers of the eyepiece and the secondary mirror lie on this same axis. Where light from the primary is reflected through a right-angle (as in the Newtonian reflector), the system is collimated when the axis of the primary mirror and the axis of the eyepiece intersect at the center of the diagonal flat mirror and are inclined to its surface by the same angle.

A collimated beam of light is one that consists of a bundle of parallel rays. A collimator is a device (lens or mirror) that produces a collimated beam. This may be achieved, in principle, by arranging for light to pass through a small aperture or pinhole placed at the focus of a lens; after passing through the lens, the emerging beam of light should consist of parallel rays.

Collisionless Processes in Astrophysical Plasmas

Plasmas, also called the fourth state of matter to distinguish them from solids, fluids and electrically neutral gases, are ionized gases. This generally implies that their thermal energy exceeds the first ionization potential such that a considerable fraction of their atoms (or molecules) is ionized, although even at lower thermal energies substantial ionization in a gas may also be produced by other processes, for instance by external radiation. It also implies that plasmas consist of free charged particles, in general positively charged ions and negatively charged electrons. Exceptions from this general rule are 'gravitational plasmas' which are dilute inert gases exposed to a gravitational field or behaving under the action of their own gravitation and showing similarities to ordinary plasmas. Other exceptions are plasmas built of electrons and positrons, positively and negatively charged ions, dusty plasmas where the dust grains may carry any amount and any sign of charges, electroweak plasmas where the interaction is mediated by massive W and Z bosons instead of photons and, finally, chromodynamic plasmas which consist of asymptotically free quarks and gluons.

All such 'plasmas' may be found in cosmic space at different locations and at different cosmological times depending on the available interaction or thermal energies. For instance, shortly after the big bang at about 10^{-10} s the plasma was in the electroweak state (see COSMOLOGY: STANDARD MODEL). With transition below 100 GeV temperature in energy units at this time the W, Z bosons became photons. Similarly, before about 10^{-4} s the cosmological temperature was high enough to allow for the chromodynamic plasma state sometimes called the quark–gluon soup. When the temperature dropped below nuclear binding energies the nuclei froze out. At temperatures well below 0.5 MeV at several seconds the plasma became ordinary plasma. This is the state we are dealing with here. Ordinary plasmas have been abundant in the universe since then until the present. However, until about 300 000 yr after the big bang all the ordinary matter in the universe was in the plasma state. After decoupling of matter from light at about this time the plasma state is still found in many, though only in localized regions, and is no longer of cosmological origin. Therefore, today, the claim sometimes made that almost all matter in the universe would be in the plasma state must be taken with care. Much of it is, in particular most of the hot matter, but by far not all of it. This is even more true as we have little idea yet what the presumably largest amount of gravitating matter in the universe, the mysterious dark matter, is really made of (see DARK MATTER: ITS NATURE).

Quasineutrality and screening

Since ionization produces equal charges of opposite signs, real plasmas are quasineutral. This means that, looked at from the outside, the plasma carries zero total (electric) charge. Embedding the plasma in an external electric field or separating one of the charge components out turns the plasma into non-neutral plasma with entirely different behavior. Looked at from the inside, the plasma is by no means electrically neutral. This is due to the high mobility of the charge carriers of which it is built. Each particle, electron or ion, is in fast thermal motion. It represents a microscopic charge density element, a microscopic current element and because of its motion a microscopic radiating antenna element. It is thus the source of an electromagnetic field. Because of this the plasma is subject not only to moving charges but also to highly fluctuating electromagnetic fields on all time and spatial scales. These electromagnetic fields act on each of the charges in the plasma giving the plasma its characteristic properties that distinguish it from the other states of matter.

Quasineutrality is an important property. It implies that the plasma volume, on average, carries equal numbers of opposite charges. However, because of their different masses, ions and electrons are usually in grossly different states of motion, with the ions nearly immobile and the electrons very fast moving. This implies that on average many electrons pass close to an ion thereby screening the electric field of the ion from the rest of the plasma. From Poisson's equation for the charge density it then follows that the electric field of an ion charge $+e$, with the elementary charge e it carries, is not felt outside a distance $\lambda_D = v_e/\omega_{pe} = (\epsilon_0 k_B T_e/n_0 e^2)^{1/2}$ from the ion. The electric potential $\phi(r)$ of the ion as function of radial distance r from the ion in the surrounding electron cloud assumes the dependence $\phi(r) = (e/4\pi\epsilon_0 r)\exp(-r/\lambda_D)$. The $1/r$ dependence is the usual Coulomb law, while the exponential describes the screening. This screening distance λ_D is the so-called Debye length. It can be written as the ratio of the electron thermal speed $v_e = (2k_B T_e/m_e)^{1/2}$ and the electron plasma frequency $\omega_{pe} = (n_0 e^2/\epsilon_0 m_e)^{1/2}$ and thus depends on the electron temperature T_e and average plasma density n_0 (k_B, m_e, ϵ_0 are Boltzmann's constant, electron mass, and free space dielectric constant, respectively).

Classification

Plasmas can be classified according to their number densities. The denser a plasma the higher is the probability that the particles collide with each other. Plasma processes under the condition of frequent collisions are called collisional. When the collisions are rare or practically absent they are called collision free. Sometimes this terminology is applied to the plasma itself, but it should be kept in mind that what is meant hereby is that the processes taking place are either slower or faster than the typical time between binary collisions in the plasma. In this spirit the degree of collisionality is defined relative to a given time scale. Hence it is not a strict definition. Because of the available long time scales, many astrophysical plasmas can be considered to be collisional. However, for a large class of sufficiently dilute plasmas even in astrophysics the time

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

scales are short enough for these plasmas to fall under the description of collisionless plasmas. Collisionless plasma processes take place in stellar winds and the interstellar medium, in the plasmas of molecular clouds, stellar atmospheres, the various magnetospheres of magnetized stars, jet plasmas and in some regions in accretion disks. Moreover, most of the processes leading to shock waves in astrophysics which are visible in either the optical or the x-ray emission belong to the class of collisionless processes or in short to collisionless plasmas.

It is also believed that the environment of black holes contains largely plasmas that are collision free for the processes taking place there. The strict definition of a collisionless process in plasma is the following. Given the time scale τ of the process under consideration and the typical frequency $\nu_c = 1/\tau_c$ of binary collisions between the particles constituting the plasma, i.e. the inverse of the time τ_c between two such collisions, a plasma is called collisionless when $\tau\nu_c > 1$. In order to determine the degree of collisionality of a plasma one thus needs to know both the Spitzer–Coulomb collision frequency ν_c and the typical time scale of the process.

Relaxation time scales

Impose an inhomogeneity or, otherwise, any deviation from thermal equilibrium onto a plasma. Because of the highly dynamical state of plasmas such deviations will readily relax, trying to get rid of the excess energy and tending to return to equilibrium conditions. Equilibria are determined by detailed force balance. In a plasma, in particular in a collisionless plasma, such a force balance is not trivially achieved. According to statistical mechanics, in thermodynamic equilibrium the distribution function should be of the canonical form of a Boltzmann energy distribution. In velocity space this distribution takes the form of a Maxwellian bell-shaped distribution function. Any deviation from this distribution will tend to be smeared out within a certain relaxation time until the distribution returns to a Boltzmannian.

The characteristic relaxation times of the various possible relaxation processes can be calculated from a Fokker–Planck equation that describes the evolution of the non-equilibrium distribution function towards thermal equilibrium. The most important relaxation time is that of approaching the Maxwellian equilibrium distribution function. There is a typical relation between the times for electrons and ions to approach such an equilibrium that can be written as

$$\tau_{ee} : \tau_{ii} : \tau_{ei} \rightarrow \left(\frac{m_e}{m_i}\right) : \left(\frac{m_e}{m_i}\right)^{1/2} : 1. \qquad (1)$$

This shows that the electrons on their own, because of their high mobility, relax after a time τ_{ee} which is faster by the root of the electron-to-ion mass ratio than the time the ions need to relax to equilibrium. Similarly, the ions relax faster by the same ratio than the total plasma, composed of ions and electrons, needs to reach one common temperature for ions and electrons. Because of this, electrons can often be described by isotropic Maxwellian distributions, while electrons and ions may have grossly different temperatures. This exchange of energy among the different components of the plasma depends on the number of collisions the particles experience. Because of the relatively long range of the Coulomb interaction in highly dilute and hot plasmas such as the astrophysical plasmas and because of the generally long astronomical time scales astrophysical plasmas on large spatial and temporal scales may sometimes not be really collisionless.

The collision frequency is defined as $\nu_c = \sigma_c n_0 \langle v \rangle$, where σ_c is the collisional cross section and $\langle v \rangle$ is the average velocity of the particles. The problem is to find an expression for σ_c. In a dilute plasma where all particles interact only via Coulomb forces, the regime applicable to astrophysical plasmas, the collisional cross section is inversely proportional to the fourth power of the thermal velocity of the particles. Hence, the collision frequency becomes $\nu_c \propto n_0/T^{3/2}$. Thus the number of collisions per second decreases rapidly with increasing temperature T (usually the electron temperature which in many cases is the higher one of the two, electron T_e and ion T_i temperatures) and with decreasing density. It is the hot dilute plasmas that tend to be collisionless. Hence, both the collisional relaxation time $\tau_c = \nu_c^{-1}$ and the mean free path of the particles, $\lambda_{\rm mfp} = \langle v \rangle/\nu_c = (n_0\sigma_c)^{-1}$ increase as $T^{3/2}$ with temperature.

Similarly to the above collision time one can define a relaxation time for the energy exchange $\tau_W = W|{\rm d}t/{\rm d}W|$ where W is particle energy, a relaxation time τ_M for the return of a small deviation of the distribution function to the Maxwellian and a relaxation time τ_{eq} for electrons and ions to achieve temperature equilibrium. Typical values for the collision frequency and the relaxation time scales for various astrophysical plasmas are given in table 1. These are based on the above binary collision frequencies.

Table 1. Collision frequencies and relaxation times.

Symbol	Expression	Conditions	Description
τ_{ce}	$0.01T_e^{3/2}/n$	$v_e \gg v_{e\rm th}$	e–e collisions[a]
τ_{ci}	$0.6T_i^{3/2}/n$	$v_i \gg v_{i\rm th}$	i–e collisions[a]
τ_{We}	$0.03T_e^{3/2}/n$		Energy relaxation
τ_{Wi}	$1.38T_i^{3/2}/n$		Energy relaxation
τ_{Me}	$0.02T_e^{3/2}/n$		Isotropization

[a] Density in cm^{-3}, temperature in K.

In the presence of an electric field $\boldsymbol{E}$ the particles experience acceleration or deceleration. For very fast particles, as mentioned above, the friction term can no longer prevent the particles from running away in the electric field. Such electric fields exist in restricted spatial regions. The fraction of electrons that escape is given by

$$\Delta n/n \approx 2.3 \times 10^{13} E_D T_e^{1/2}/\exp{(8E_D/E)^{1/2}} \qquad (2)$$

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

where $E_D \approx 4 \times 10^{-10} Z n_e T_e^{-1}$ is the Dreicer electric field, another fundamental parameter of the plasma. For small electric fields no particles will run away, but the larger the electric field becomes the more particles will escape collisional confinement and leave the position to form beams or extended tails on the distribution function.

Description of plasmas

Plasmas without collisions must be treated within full kinetic theory. This implies that one has to solve the combined Vlasov–Maxwell system of equations for both electrons and ions. This system of equations is extraordinarily involved. The Vlasov equation is the collision-free one-particle Boltzmann equation which, given the Hamiltonian $\mathcal{H}(\boldsymbol{p}, \boldsymbol{x}, t)$ and defining the one-particle probability distribution function $f(\boldsymbol{p}, \boldsymbol{x}, t)$, is

$$\partial_t f + \{\mathcal{H}, f\} = 0 \tag{3}$$

where the braces are Poisson brackets and $\boldsymbol{p} = m\gamma_r \boldsymbol{v}$ is the particle momentum, γ_r the relativistic γ factor, $\boldsymbol{v}$ particle velocity and $\boldsymbol{x}$ position. The explicit version of this equation neglecting gravity becomes

$$\partial_t f + \boldsymbol{v} \cdot \boldsymbol{\nabla} f + \frac{q}{m}(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B}) \cdot \boldsymbol{\nabla}_v f = 0 \tag{4}$$

where $\boldsymbol{\nabla}_v \equiv \partial/\partial \boldsymbol{v}$ is the gradient in velocity space. The electric and magnetic fields appearing in equation (4) are related to the distribution function f via the expressions

$$\rho_q = \sum_{i=e,i} q_i \int \mathrm{d}^3 \boldsymbol{v}\, f_i \tag{5}$$

$$\boldsymbol{j} = \sum_{i=e,i} q_i \int \mathrm{d}^3 \boldsymbol{v}\, \boldsymbol{v} f_i \tag{6}$$

for the electric space charge ρ_q and current $\boldsymbol{j}$ densities. These enter the electrodynamic (Maxwell) equations

$$\nabla \times \boldsymbol{B} = \mu_0 \boldsymbol{j} + c^{-2}\, \partial_t \boldsymbol{E} \qquad \nabla \cdot \boldsymbol{B} = 0$$

$$\nabla \times \boldsymbol{E} = -\partial_t \boldsymbol{B} \qquad \boldsymbol{\nabla} \cdot \boldsymbol{E} = \rho_q/\epsilon_0. \tag{7}$$

Solutions of this extremely complicated set of equations can be found only in the most simple cases. However, whenever one of the physical time scales is much longer than the relaxation times, the collisions are frequent enough to allow for a fluid description. In such a description the fluid variables (density n, bulk velocity $\boldsymbol{u}$, pressure tensor $\mathbf{P}$, etc) are defined as the ascending moments

$$\mathcal{M}_i^{(i)} = \int \mathrm{d}^3 \boldsymbol{v}\, \boldsymbol{v} \ldots_{(i \text{ times})} \boldsymbol{v} f_i. \tag{8}$$

Under such conditions the plasma can be treated within the MAGNETOHYDRODYNAMIC (MHD) approach which is strictly valid only in the strongly collisional state. Collisionless MHD is, strictly speaking, a contradiction in itself when applied to plasmas even though it has found extensive application and led to many useful results.

A fluid description may also result for collision-free plasmas when some ordering process is at work that forces the particles to behave fluid like. Gyration around a strong magnetic field may have such an effect. This then leads, under certain conditions, to the so-called Chew–Goldberger–Low anisotropic MHD. Also, collisionless plasmas very frequently generate internal correlations, turbulent interactions and other effects that force the plasma particles to exert collective behavior. In such cases the ordinary binary collisions are replaced by so-called 'anomalous' collisions that may also allow for a fluid description. Anomalous collisions are a consequence of plasma wave turbulence.

Generalized Ohm's law

Because of the enormous mass differences between electrons and ions $m_e/m_i = 1/1836$ it is sometimes convenient to consider only the dynamics of the ions. This applies when considering processes that change on a much longer time scale $\tau = \omega^{-1}$ than the electron plasma oscillation time ω_{pe}^{-1} or $\omega \ll \omega_{pe}$. In this case the electron dynamics partially decouples from that of the ions. The momentum equation for electrons can then be used as the definition equation for the electric field. Rearranging it in order to express $\boldsymbol{E}$ through the electron quantities one has

$$\boldsymbol{E} + \boldsymbol{u}_e \times \boldsymbol{B} = -\frac{m_e \nu_c}{e}(\boldsymbol{u}_e - \boldsymbol{u}_i) - \frac{1}{en}\boldsymbol{\nabla} \cdot \mathbf{P}_e - \frac{m_e}{e}\frac{\mathrm{d}\boldsymbol{u}_e}{\mathrm{d}t} \tag{9}$$

which is an extended form of Ohm's law. Here $\boldsymbol{u}$ is the bulk velocity and $\mathbf{P}$ the pressure tensor. Introducing the current density $\boldsymbol{j} = e(\boldsymbol{u}_i - \boldsymbol{u}_e)$, equation (9) assumes the ordinary form

$$\boldsymbol{E} + \boldsymbol{u} \times \boldsymbol{B} = \eta \boldsymbol{j} - \frac{1}{en}\boldsymbol{j} \times \boldsymbol{B} - \frac{1}{en}\boldsymbol{\nabla} \cdot \mathbf{P}_e - \frac{1}{\epsilon_0 \omega_{pe}}\frac{\mathrm{d}\boldsymbol{j}}{\mathrm{d}t} + \frac{m_e}{e}\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}. \tag{10}$$

Here $\boldsymbol{u}$ is to good approximation the center-of-mass velocity, $\eta = \nu_c/\epsilon_0 \omega_{pe}^2$ the resistivity and the second term on the right-hand side is the Hall term. In a collisionless plasma the first term disappears, and Ohm's law is entirely governed by the Hall term, the electron pressure gradient and the electron inertia in the two last terms, while the left-hand side of equation (10) describes the frozen-in property (see below) widely used in MHD. The terms on the right of Ohm's law modify this condition to a large extent in a real collisionless plasma. The Hall term introduces effects of non-coplanarity, helicity and anisotropy, while the pressure gradients and in particular the inertial terms may violate the frozen-in state.

Properties of collisionless plasmas

Neglecting collisions in the plasma implies that the plasma is ideally conducting. This should not be confused with the plasma being superconducting, however. On the contrary, ideal plasmas may contain magnetic fields, and these fields cannot be expelled from the plasma because they are frozen in into the plasma. In order to pull the magnetic field out, the frozen-in condition has to be broken at least locally by generation of anomalous resistivities that destroy the non-collisionality.

Frozen-in concept

The frozen-in property follows from the universal validity of Faraday's law $\nabla \times \boldsymbol{E} = -\partial \boldsymbol{B}/\partial t$ even for the plasma, and from the (simplified) Ohm's law $\boldsymbol{E} + \boldsymbol{u} \times \boldsymbol{B} = \eta \boldsymbol{j}$. The latter gives the proportionality between the electric field $\boldsymbol{E}$ and the current density $\boldsymbol{j}$. The coefficient is the resistivity $\eta = m_e \nu_c / n_0 e^2$ which itself increases with collision frequency. The left-hand side of Ohm's law is a simple consequence of the Lorentz transformation in moving media. Taken together these two equations lead to the fundamental induction equation for a conducting and moving medium such as a plasma:

$$\frac{\partial \boldsymbol{B}}{\partial t} = \nabla \times \boldsymbol{u} \times \boldsymbol{B} + \frac{\eta}{\mu_0} \nabla^2 \boldsymbol{B}. \qquad (11)$$

This equation shows that for $\eta \to \infty$ the magnetic field in the plasma moving with velocity $\boldsymbol{v}$ is zero which implies that in the moving frame the magnetic field does not change in time and hence, as argued above, is frozen in into the plasma.

Gyration

Physically this implies that in the moving frame the plasma particles themselves are tied to the magnetic field lines, gyrating around them in circles of radius $r_B = v_\perp / \Omega$ and gyration period $\tau_B = 2\pi/\Omega$. The gyration frequency is given by $\Omega = eB/m$ and is proportional to the magnetic field. This gyration is simply imposed on the charges by the Lorentz force $\boldsymbol{F}_\mathrm{L} = \pm e \boldsymbol{v} \times \boldsymbol{B}$. Locally it is perpendicular to the magnetic field $\boldsymbol{B}$ and particle velocity $\boldsymbol{v}$. It does not perform work on the particles. It therefore conserves particle energy and merely turns the component of the particle velocity perpendicular to the magnetic field into a circular orbit around $\boldsymbol{B}$.

Breaking the frozen-in condition

In order to take the plasma particles away from the magnetic field in collisionless plasma one thus needs anomalous processes. They generate anomalous transport coefficients. Presumably, in all collisionless astrophysical plasmas such processes are at work. Otherwise, the frozen-in property can also be broken by extraordinarily steep gradients in density, temperature, composition or magnetic field in the plasma. Their length scales must be of the order of the gyroradii of the particles involved. Compared with all astrophysical scales, these are enormously small (see table 2). Gradients on these scales are thus not only unobservable but probably also unrealistic. The main mechanism which leads to anomalous transport in a collisionless plasma is the turbulence.

Turbulence is generated via the excitation of plasma waves. Wave excitation proceeds via instabilities. There is an enormous number of possible instabilities in collisionless plasmas depending on the nature of the free-energy sources available, i.e. weak inhomogeneities, beams, jets, shear in field and velocity, electric currents, external forces exerted on the plasma and so on. Each of the instabilities excites a limited range of frequencies ω and wavevectors $\boldsymbol{k}$ which are mutually related by the dispersion relation $\omega = \omega(\boldsymbol{k})$.

Plasma waves

Because of its finite and relatively high temperature, the plasma is a thermally active medium. This means that the velocities of the particles constituting the plasma cover a wide range in velocity space, each of the particles being capable of absorbing or spending energy in interaction with an electric field fluctuation. In general, a particle that is moving at lower speed than the phase velocity of such fluctuations will be pushed by the wave and will absorb fluctuation energy. This leads to wave damping. On the other hand, a particle moving faster than the wave will push the wave and increase the fluctuation energy. Because of this nature it is clear that only a restricted number of wave modes can propagate in plasma. These are the modes that are very weakly absorbed by the plasma particles. The dispersion relations for the allowed waves can be found from an eigenvalue solution of the system of basic equations linearized around the equilibrium. Clearly, there will always be weak collisionless (or Landau) damping, for some of the particles will always be slow with respect to the wave and will absorb wave energy. However, in many cases this damping is so weak that it can be neglected.

When speaking of such wave modes or fluctuations it is not meant that the waves are all electromagnetic in nature as in ordinary electrodynamics. The property of the plasma of being an active medium implies that entirely new wave modes can evolve in the plasma body or at its surface. These modes are unknown in free space, and most of them cannot leave the plasma but are confined to the plasma. The large variety of such possible modes reaches from sound waves and purely electrostatic fluctuations on the electron and ion scales to all kinds of electromagnetic fluctuations, purely magnetic fluctuations of long wavelengths, and mixed magnetoacoustic waves.

The almost absolute invisibility of the majority of plasma waves looked at from a remote position as is common in astrophysics presents an enormous difficulty for astrophysics in inferring anything about the very nature of interactions in a collisionless astrophysical plasma. Any information must necessarily rely on secondary effects leading to the observation of radiation that can be detected on Earth. Since no *in situ* observations on any astrophysical object will ever be possible the true processes will forever be hidden to us. It is therefore of vital interest to infer information about the effects collisionless plasma processes may have on the radiation emitted from such objects. Unfortunately, very little is known about such effects at the current time.

Radiation

The most desirable effect is the direct emission of radiation in a certain wave band from that one may make

inferences about the emission mechanism and hence the state of the collisionless plasma at the source. Here we are not interested in the ordinary *synchrotron* or *bremsstrahlung* (free–free) emissions. The former is emitted by energetic charged particles that gyrate in a magnetic field configuration. It allows us to map the remote magnetic fields in direction and magnitude. The latter, being emitted from very hot weakly *collisional* plasmas, permits the determination of the hot temperature and density at the location of the emitting source.

The important processes taking place in collisionless plasmas are without exception based on the assumption of instability, generation of plasma waves and interaction of these waves among themselves or with the particle constituents. There are only very few cases when these interactions directly lead to emission of radiation. Such cases are restricted mainly to two processes: the maser amplification of radiation in strongly magnetized very dilute plasmas containing a weakly relativistic trapped particle component, the so-called *electron cyclotron maser* mechanism, and radiation from fast electron beams passing through a dense, hot but otherwise relatively weakly magnetized plasma. Cyclotron maser emission is restricted to underdense plasmas satisfying the condition $\omega_{pe}/\omega_{ce} < 1$, which is satisfied only in strong magnetic fields. Since large-scale magnetic fields are usually weak in astrophysics, this condition restricts it to the vicinity of strongly magnetized objects. Examples of such processes are found in interplanetary space in the non-thermal radio emissions from the Sun and the planets. In astrophysics similar processes are expected to take place in the very strongly magnetized pulsar magnetospheres, the coronae of magnetized stars and possibly also in radio or x-ray jets ejected from massive objects.

Collisionless plasma processes play a key role also in a number of other effects such as the acceleration of small groups of charged particles into energetic beams and possibly plasma jets, the formation of collisionless shock waves, the magnetic reconnection process and the generation of anomalous transport. In order to describe these phenomena a brief discussion of the plasma instability and turbulence mechanisms follows.

Plasma instability and turbulence

In particular cases when the particle distribution function deviates from the Maxwell–Boltzmann distribution, the plasma undergoes instability. Because the plasma is thermally active, it contains a bath of spontaneously excited thermal noise of all wavelengths. At given temperature T the level of fluctuation never falls below this thermal level with the latter given by the Stefan–Boltzmann law. Decreasing the fluctuation level thus requires cooling of the plasma by means of adiabatic expansion or radiative losses in cases when the plasma is optically thin to the radiation or from its surface as in the case of thermal bremsstrahlung radiation.

Linear wave growth

The instability picks a particular range of wavelengths and frequencies out of the thermal noise and lets it grow in time and space. For one single mode of wavevector $\boldsymbol{k}_0$ out of this range, the energy density of the thermal noise level is $W_0 \equiv \frac{1}{2}\epsilon_0|\boldsymbol{E}_0|^2 + \frac{1}{2}|\boldsymbol{B}_0|^2/\mu_0$. Since the linear wave mode $[\boldsymbol{E}(t,\boldsymbol{x}), \boldsymbol{B}(t,\boldsymbol{x})] \propto \exp(-\mathrm{i}\omega t + \mathrm{i}\boldsymbol{k}_0 \cdot \boldsymbol{x})$, the energy density in the mode grows with time as

$$W(\boldsymbol{k}_0, t) = W_0(\boldsymbol{k}_0)\exp[2\gamma(\boldsymbol{k}_0)t] \tag{12}$$

where, for instability, the growth rate $\gamma(\boldsymbol{k}_0)$ is the positive imaginary part of the wave frequency. It is the main goal

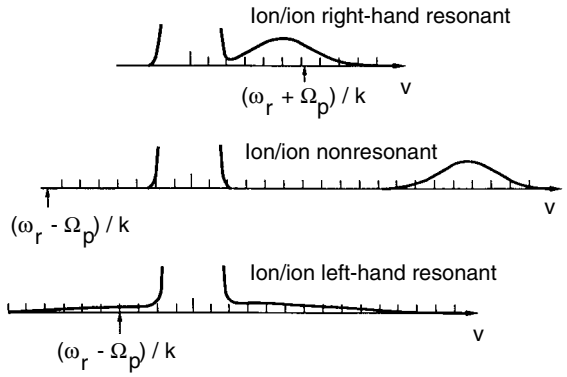

Figure 1. Reduced ion distribution functions corresponding to three electromagnetic ion–ion beam instabilities and associated cyclotron resonant velocities (after Gary, 1993).

of *linear plasma theory* to calculate $\gamma(\boldsymbol{k}_0)$. The growth rate itself is a function of the wave frequency, wavenumber and the properties of the free-energy source. The exponential growth of the wave given by the growth rate has a number of important effects. First, it readily depletes the energy of the free-energy source and transforms it into electromagnetic energy unless the source is continuously re-established. Second, the wave energy for exponential growth readily reaches a level that is comparable with the local kinetic energy level $n_0 k_B T$ of the plasma itself. Once this happens, linearity is violated, unless the wave energy is transported away by some process such as wave propagation or convection on a time scale faster than the wave grows. The plasma then enters the non-linear state.

An example of an electromagnetic instability occurring at collisionless shocks is the ion–ion beam instability. Whenever two ion components have a drift velocity v_d greater than some threshold, the corresponding free energy can lead to instability growth. Let us assume, for simplicity, that the two ion components, in the case of a shock the upstream plasma representing the core and the backstreaming ions representing the beam, are drifting Maxwellians. There are three electromagnetic instabilities that may arise from such a configuration: the right-hand resonant, the non-resonant and left-hand resonant ion–ion instabilities. Figure 1 shows schematically the ion distribution function (core and beam) corresponding to the three instabilities and the associated cyclotron resonant speeds. At low densities and low drift velocities the ion–ion right-hand resonant instability is the growing mode of lowest threshold. The waves propagate in the direction of the beam. In the limit of zero drift velocity this mode is the right-hand circularly polarized positive helicity mode on the magnetosonic whistler branch. In the case of large beam velocities and high beam densities a non-resonant instability is possible. When the beam has a large temperature, the left-hand instability is possible where the waves are resonant with those beam ions which have velocity (in the core frame) opposite to the beam velocity.

Nonlinear effects

In the non-linear state large-amplitude waves start decaying into sidebands, thereby broadening the spectrum. They may interact with other waves transforming energy into remote parts of $\boldsymbol{k}$-space. They may exert radiation pressure on the plasma, causing modulation of their propagation properties. This introduces ripples into the plasma. The waves can be trapped, reflected and become modulated in wavelength. They also may interact with the particle component. Low-energy particles in the wave frame can become trapped in the potential wells of the wave and transported away, thereby becoming accelerated by the wave until they are injected from the wave into the plasma as beamlets. Particles can be reflected from the wave and become accelerated to moderate and high energies in a kind of Fermi process. Some of these processes modify the properties of the collisionless plasma in such a way that anomalous collisions are caused.

The plasma containing a high level of the kind of turbulence described above presents a large number of hurdles for a test particle that tries to pass across the plasma. The particles will be scattered at waves, become trapped, becoming untrapped after a certain time, energized or decelerated. All these processes modify the free-particle orbit and lead to scattering of the particle in energy, path and pitch angle. In a more macroscopic description this process can be described as anomalous transport. All active collisionless plasmas thus exhibit anomalous transport properties. In each single case it is, however, extremely difficult to determine the kind of anomalous transport that is realized in the plasma under the particular conditions. In fact, the whole problem of anomalous transport remains to be solved. It is therefore safe to say that we do not know what the transport properties of collisionless astrophysical plasmas really are. Only in a few simple limits, in particular the quasilinear one, have such collisionless 'anomalous' transport coefficients so far been derived.

It should be added that on the long temporal and large spatial scales one encounters in astrophysical applications any plasma process will always have long reached the quasi-stationary and highly saturated non-linear state of fully developed turbulence. Since this is a natural fact one must be very cautious in applying linear plasma theory in astrophysics. Since a fully non-linear theory of plasma turbulence does not exist, this considerably obscures the astrophysical application of plasma physics.

Anomalous transport

The transport coefficients (resistivity, heat conductivity etc) entering the fluid description of plasmas have to be calculated within the fully developed turbulence theory. Within a first and lowest level approximation this is usually done for selected cases in the framework of quasilinear theory. The philosophy of this theory is straightforward.

Fokker–Planck approach

Consider an instability that excites linearly growing waves of frequency $\omega(k)$ in a certain waveband of width $\Delta\omega$, Δk. The growth rate is $\gamma(\omega, k)$. Once these waves reach substantial amplitude their presence cannot be neglected any more energetically in comparison with other energy sources and in particular with the free energy driving the instability. In such a case the waves start reacting on the plasma and the free energy. The simplest effect is a quenching of the instability by the waves leading to saturation at a level that is determined by equation (12) with vanishing growth rate. The growth rate $\gamma[f(\boldsymbol{v}, t)]$ itself depends functionally on the modified distribution function $f(\boldsymbol{v}, t)$ which for its part evolves according to the Fokker–Planck equation. Writing this as

$$\partial_t f = \partial_v \cdot \mathbf{D}(W, \gamma, \boldsymbol{v}) \cdot \partial_v f \tag{13}$$

and knowing the explicit form of the velocity space diffusion coefficient $\mathbf{D}(W, \gamma, \boldsymbol{v})$, the expressions for W, γ, $\mathbf{D}$ together with the evolution equation (12) for $W(t)$ and the Fokker–Planck equation (13) form a closed system from which $f(t \to \infty)$ and $W(t \to \infty)$ can be determined. Once the final wave energy density $W(\infty)$ is known, it determines the anomalous collision frequency. This can be seen from the fact that the classical Coulomb collision frequency

$$\nu_c \propto \frac{\omega_{pe}}{n\lambda_D^3} = \frac{\omega_{pe} W_0}{n k_B T} \tag{14}$$

can be expressed in terms of the wave energy W_0 in the thermal fluctuations. Replacing W_0 with $W(\infty)$ gives the estimate (with α a numerical coefficient)

$$\nu_{\rm an} = \alpha \omega_{pe} \frac{W(\infty)}{n k_B T} \tag{15}$$

for the anomalous collisions.

Non-magnetized case

In non-magnetized plasmas (or in one-dimensional plasmas with the direction of current parallel to the magnetic field $\boldsymbol{B}$) the dominant current instability is ion acoustic wave turbulence. In this case one finds the Sagdeev formula

$$\nu_{\rm an,ia} = 0.01 \omega_{pi} \frac{v_d}{c_{ia}} \frac{T_e}{T_i}. \tag{16}$$

Here $\omega_{pi} = (m_e/m_i)^{1/2}\omega_{pe}$ is the ion plasma frequency, $c_{ia} = (k_B T_e/m_i)^{1/2}$ is the ion acoustic wave velocity and $v_d = |\boldsymbol{j}/en|$ is the current drift velocity. This formula demonstrates that the anomalous collision frequency can be large in dense plasmas of high plasma frequency carrying strong currents and containing hot electrons.

Magnetized case

In magnetized plasmas a variety of other wave modes may contribute to the generation of anomalous collisions and transport. Within the quasilinear approach the most important are those instabilities which are caused by macroscopic gradients in density, magnetic field and temperature leading to so-called drift instabilities. Their typical oscillation frequency is mediated by a combined motion of ions and electrons, the lower-hybrid resonance $\omega_{lh} \approx (\omega_{ce}\omega_{ci})^{1/2} = \omega_{ce}(m_e/m_i)^{1/2}$, and the anomalous collision frequency becomes

$$\nu_{{\rm an},lh} \approx \left(\frac{\pi}{2}\right)^{1/2} \left(\frac{r_{ci}}{4L_\nabla}\right)^2 \omega_{lh}. \tag{17}$$

Here, L_∇ is the relevant gradient scale, and r_{ci} is the thermal ion gyroradius. These collision frequencies can become very large, of the order of ω_{lh} itself. They can cause substantial plasma diffusion close to Bohm diffusion $D_B = k_B T_e/16eB$. Microscopic plasma turbulence is thus capable of substantially changing the transport properties of a collisionless plasma. Quasilinear theory may in many cases be superseded by other strongly non-linear effects, such as particle trapping in large-amplitude wave fields, modulation of the plasma by the 'radiation pressure' of the large-amplitude waves, coherent interactions and non-linear wave–particle interactions that are not included in the above theory. Moreover, in relativistic plasma radiation cooling of the electrons may modify the conditions and induce high-ion-temperature instabilities. These lead to low-frequency electromagnetic turbulence that results in plasma vortices and mixing effects.

Reconnection

MAGNETIC RECONNECTION (figure 2) is among the most important applications of anomalous transport. Reconnection describes the merging of two oppositely directed magnetic fields across the current sheet that separates them in highly conducting plasma. This problem is of marked importance for astrophysical plasma physics. Reconnection has two effects: it changes the magnetic field topology and it leads to bulk plasma acceleration.

In vacuum reconnection does not provide any difficulties as the magnetic flux can rearrange in arbitrary ways. However, in ideally conducting collisionless plasmas merging of two oppositely directed magnetic field configurations approaching each other is inhibited by the frozen-in condition. When the plasma is collisional, merging is made possible in some narrow region, the so-called diffusion region, by the diffusive (last right-hand) term in equation (11). The initially anti-parallel fields diffuse across the diffusion region and rearrange into an X-type configuration. The two formerly unconnected field lines become suddenly connected. What is much more important, however, is that plasmas to both sides of the current layer that before merging could not mix after reconnection find themselves on the same field line and will mix along the field even outside the diffusion

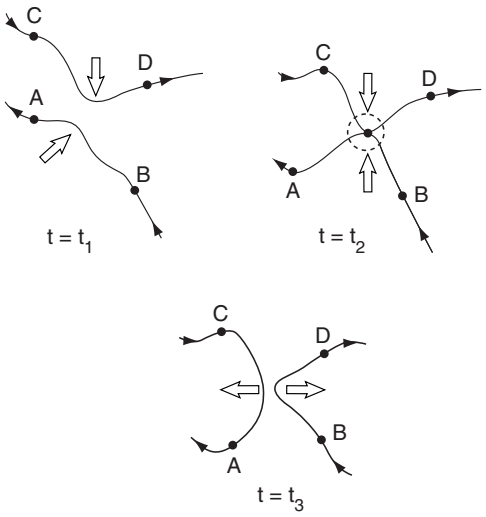

Figure 2. The schematics of the sequential change in magnetic topology and plasma acceleration during reconnection. The dashed circle surrounds the diffusion region. Plasmas initially (time $t = t_1$) on two separate field lines (A and C, B and D) are found on the same field line after reconnection took place ($t = t_3$). Field line stresses are released and converted into bulk plasma acceleration as indicated by the open arrows.

region. In addition, the strong bending of the newly connected field lines in the current sheet causes magnetic stresses that tend to relax and accelerate the bulk plasma up to flow velocities of the order of the Alfvén velocity, $v_a = B/(\mu_0 n m_i)^{1/2}$. In the so-called Petschek model of reconnection two standing slow-mode waves extend from the diffusion region and define the wedge-shaped high-speed flow region. Most of the acceleration actually occurs in these slow-mode shocks. The Petschek model is based on a fluid (MHD) picture. In a collisionless plasma it is not clear whether or not such slow-mode shocks actually form during the reconnection process. In the small diffusion region the Joule dissipation causes local heating of the plasma, and the electric field generated in the reconnection process further accelerates groups of particles up to high energies.

In a collisionless plasma a deviation from non-ideality can support reconnection in the diffusion region. Such a non-ideality may be provided by anomalous resistivities based on anomalous collision frequencies. This requires strong currents and/or plasma gradients until the current instabilities exceed the threshold. However, collisionless reconnection can also proceed without anomalous resistivity. Within the region close to the X-line the ions can be considered to be unmagnetized. The frozen-in condition for the electrons can be broken by the electron inertia and/or by a non-gyrotropy of the electron particle distribution function in the X-line environment.

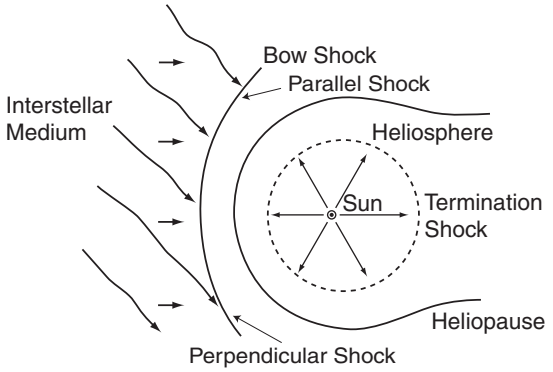

Figure 3. The heliospheric bow shock resulting from interaction of the heliospheric system with the interstellar medium: an example of a collisionless shock. In the upper part of the figure the shock is quasiparallel (magnetic field lines normal to shock); in the lower part it is quasiperpendicular (field lines tangential to shock). Inside the heliosphere a termination shock appears: the termination shock of the solar wind.

Collisionless shocks

Another important field of application of collisionless plasma theory is the dissipation in collisionless shocks. An example of a collisionless shock system is shown in figure 3. It consists of the termination shock of the solar wind resulting from the interaction between the highly supersonic solar wind stream and the interstellar medium. In addition a bow shock is produced outside but in front of the heliopause by its motion through the interstellar cloud.

Sub- and supercritical shocks

In this case the anomalous transport processes are of lesser importance. In a collisional plasma the width of the shock transition is of the order of the collisional mean free path. This is too large by many orders of magnitude in collisionless plasma where the shock transition is typically a few ion inertial lengths, c/ω_{pi}. The physics of collisionless shocks depends on essentially three parameters, the upstream magnetosonic Mach number $M = u/(v_A^2 + c_{ia}^2)^{1/2}$, the angle θ_{Bn} between the upstream magnetic field and the shock normal, and the chemical composition of the plasma. According the the Mach number one distinguishes subcritical ($M < M_c$) and supercritical ($M > M_c$) shocks. The critical Mach number $M_c = u_d/c_{ia,d}$ is defined as the ratio of the downstream velocity to the ordinary downstream (index d) sound speed. With respect to θ_{Bn} one distinguishes quasiperpendicular ($\theta_{Bn} > 45^\circ$) and quasiparallel ($\theta_{Bn} < 45^\circ$) shocks. For perpendicular shocks the critical Mach number is $M_c = 2.76$. It decreases with increasing angle θ_{Bn}. The chemical composition may lead to weakening of the shock profile.

In subcritical shocks the anomalous collisional dissipation in the shock front caused by micro-instabilities generated there is roughly sufficient for the required increase in entropy, heating and generating the turbulent disorder behind the shock that leads to dissipation of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

excess upstream energy stored in the flow. In supercritical shocks the flow energy supply to the shock from upstream is too fast. The instabilities in the shock front do not have sufficient time to evolve to a level sufficiently high for effective dissipation. In this case the shock front acts like a mirror and starts reflecting ever more ions and electrons back upstream into the onstreaming flow. In this case it becomes vital to distinguish between quasiperpendicular and quasiparallel shocks. This is important because in collisionless plasma the particles are tied to the magnetic field and can only move along the magnetic field. This implies that in quasiperpendicular shocks the reflected particles stay at the shock front or are convected back into the downstream region. The upstream width of the region containing the reflected particles is of the order of the average gyroradius of the reflected particles.

Quasi-perpendicular shocks

The specularly reflected and subsequently gyrating particles cause a foot-like signature in any *in situ* recording of $\boldsymbol{B}$. During this gyration the specularly reflected ions are accelerated in the $\boldsymbol{v} \times \boldsymbol{B}$ electric field to about twice the upstream bulk speed. Since these ions remain to be tied to the magnetic field, they become convected with the magnetic field into the downstream region. The region immediately behind the shock ramp contains the transmitted distribution plus the accelerated and transmitted specularly reflected ions.

The transmitted specularly reflected ions gyrate in bunches around the magnetic field lines. Such distributions are unstable with respect to the generation of plasma waves. They excite waves that in the downstream region lead to dissipation and plasma heating. In high Mach number shocks, as well as in shocks of supernova remnants, the interaction of specularly reflected ions with background electrons in addition excites ion acoustic waves which may give rise to rapid anomalous heating of the electrons in the shock ramp.

Quasi-parallel shocks

In the case of a quasiparallel shock the situation is dramatically different. Here the reflected particles can move far upstream along the magnetic field into the onflowing stream. Since at the same time the field is convected downstream toward the shock, this is true for particles having velocities along $\boldsymbol{B}$ higher than the speed of the flow.

Such fast particles form a counterstreaming beam in the flow and excite beam–beam instabilities in the otherwise undisturbed super-magnetosonic supercritical flow. These instabilities evolve into large-amplitude turbulence which is continuously convected towards the shock. The region filled with this turbulence is called foreshock. Since the foreshock is turbulent, energy is dissipated here, and the flow is slightly decelerated. Thus the foreshock effectively marks the grossly widened shock transition.

When the low-frequency upstream waves are convected with the flow into the shock they interact with upstream energetic particles and steepen into large-amplitude pulsations. The shock itself can be viewed as a patchwork of such large-amplitude pulsations which pile up and determine the downstream plasma state.

In the case of more parallel shocks the interaction of the upstream plasma with the hot downstream plasma in the region of overlap at the shock ramp also causes an ion–ion beam instability. The waves generated by this so-called interface instability are confined to the region downstream of the shock transition where they contribute to dissipation and heating. The wavelength of the interface waves increases with increasing shock Mach number. In the low to medium Mach number regime the interface waves have small wavelengths and are damped within a short distance downstream. At higher Mach number shocks the interface waves have large wavelengths and determine the downstream turbulence. In parallel shocks the downstream state is thus determined by the upstream turbulence. Quasiparallel shocks are thus highly non-stationary and oscillatory with the main dissipation provided by the shock interaction with the upstream waves in place of the microturbulence in the shock ramp itself. This shows that in collisionless plasmas the mechanism for shock formation is very different from that of collisional fluids.

Particle acceleration

An important field in collisionless plasma astrophysics is the mechanism of acceleration of particles to high energies. Collisionless shocks are among the main agents for accelerating ions as well as electrons to high energies whenever sufficient time is available. Particles reflected from the shock and from scattering centers behind the shock in the turbulent compressed region when coming back across the shock into the turbulent upstream region have a good chance to experience multiple scattering and acceleration by first-order Fermi acceleration. Second-order or stochastic Fermi acceleration in the broadband turbulence downstream of collisionless shocks will contribute to acceleration. In addition, ions may be trapped at perpendicular shocks. The trapping forces are provided by the electrostatic potential of the shock and the Lorentz force excerted on the particle by the magnetic and motional electric fields in the upstream region. With each reflection at the shock the particles gyrate parallel to the motional electric field, picking up energy and surfing along the shock surface. All these mechanisms are still under investigation, but there is evidence that shocks play a most important role in the acceleration of cosmic rays and other particles to very high energies.

In addition to acceleration in shocks one expects that particles are also accelerated in the reconnection region. Despite the shocks, collisionless plasmas are capable of generating large potential differences along the magnetic field. These are known as double layers or electrostatic shocks. In most cases the potential will not consist of

a continuous drop but will compose itself of myriads of little microscale or mesoscale potential drops confined to cavitons, solitary wave structures or phase space holes generated in non-linear wave–particle interaction. The plasma divides itself into several components which either support these structures or destroy them by transit time damping leading to acceleration.

Concluding remarks

There is no *in situ* information available from astrophysical plasmas. So one is forced to refer to indirect methods and analogies with accessible plasmas. Such plasmas are found only in near-Earth space. Actually, most of the ideas about and models of the behavior of astrophysical plasmas have been borrowed from space physics and have been rescaled to astrophysical scales. Measurements and models developed for the description of space plasmas often serve as paradigms for astrophysical plasmas. These models encompass stellar wind flows, pulsar magnetospheres, magnetospheres of magnetized stars and other planets including extra-solar planets, magnetospheres near black holes, the interaction of stellar winds with the surrounding INTERSTELLAR MATTER, expansion of SUPERNOVA REMNANTS, the whole domain of reconnection, collisionless shocks, plasma jets, and some non-thermal radiation mechanisms.

However, the large spatial and long temporal scales in astrophysics and astrophysical observations do not allow for the resolution of the collisionless state of the plasmas. For instance, in the solar wind the collisional mean free path is of the order of a few AU. Looked at from the outside, the heliosphere (figure 3), the region which is affected by the solar wind, will thus be considered collision dominated over time scales longer than a typical propagation time from the Sun to Jupiter. On any of the smaller and shorter scales this is wrong, because collisionless processes govern the solar wind here. Similar arguments apply to stellar winds, molecular clouds, pulsar magnetospheres and the hot gas in clusters of galaxies. One should thus be aware of the mere fact of a lack of small-scale observations. Collisionless processes generate anomalous transport coefficients. This helps in deriving a more macroscopic description. However, small-scale genuinely collisionless processes are thereby hidden. This implies that it will be difficult, if not impossible, to infer anything about the real structure, for instance, of collisionless astrophysical shock waves. Similarly, the processes of non-thermal radiation and acceleration, and the kinetic behavior of the gas in clusters of galaxies, are only accessible by exploiting the analogy with accessible collisionless plasmas in the close environment of the Earth and the heliosphere. From a theoretical point of view, collisionless plasma processes require the solution of the collision-free Boltzmann equation (Vlasov equation) combined with the full set of Maxwell's equations. This is a formidable task; it is often easier to perform particle-in-cell simulations of such processes where macro-ions and electrons are followed in time in the self-consistently calculated magnetic and electric fields. If only low-frequency processes are studied, the electrons are often approximated as a fluid and only the ions are treated as particles (hybrid simulation method).

Bibliography

The literature about collisionless astrophysical plasmas is sparse. Sporadic information can be found in the following proceedings:

Colombo, Giuseppe ('Bepi') (1920–84)

Colombo was a mathematician and engineer, born in Italy, professor at the University of Padua. He explained the peculiar rotation of Mercury. The planet turns three times during two revolutions around the Sun, in a previously unsuspected resonance (see MERCURY). Using this feature, Colombo discovered the orbital maneuver that enabled Mariner 10 (see MARINER MISSIONS) to pass close to Mercury three times in 1974–75. He proposed this manoeuver to NASA, and tripled the value of the mission. Colombo is also famous for his development of the concept of space tethers. While space-based tethers have been studied theoretically since early in the 20th century, Colombo invented the idea of using a long tether to support a satellite from an orbiting platform in a gravitationally stabilized system. He designed the tethered satellite system (TSS) to investigate plasma physics and the generation of electricity in the upper atmosphere. Two technology tests of a tether system, TSS-1 and TSS-1R, were carried out in July 1992 and February 1996 by Italy using the NASA Shuttle. In the more recent test, the tether deployed to 20 km but broke without useful result. The ESA mission to Mercury scheduled for 2009 is named Bepi Colombo in affectionate recognition of his contributions.

Columba

(the Dove; abbrev. Col, gen. Columbae; area 270 sq. deg.) A southern constellation which lies between Lepus and Pictor, and culminates at midnight in mid-December. It represents Noah's dove and was introduced by the Dutch theologian and geographer Petrus Plancius, who formed it from stars to the south of Canis Major and included it on a celestial chart in 1592.

A small, inconspicuous constellation, the brightest stars in Columba are α Columbae (Phact), magnitude 2.6, and β Columbae (Wazn), magnitude 3.1. There are three other stars of magnitude 4.0 or brighter. Interesting objects include μ Columbae, a famous 'runaway star', which is one of three stars (the other two being 53 Arietis and AE Aurigae) that are diverging at high velocity ($\sim$120 km s^{-1}) from a point in Orion from which they are thought to have been ejected as a result of a supernova explosion a few million years ago, and NGC 1851, a seventh-magnitude globular cluster.

Coma

The distortion of off-axis images produced by lenses or mirrors. Rays of light that enter a lens, or reflect from a mirror, at an angle to its optical axis (the line passing perpendicularly through the center of the lens or mirror), form pear-shaped images. The magnitude of the distortion increases with increasing distance from the optical axis. This particular optical aberration derives its name from the 'comet-like' appearance of such images.

A spherical mirror does not suffer from coma but does suffer from spherical aberration. If the latter is corrected, by deepening the curve of the mirror's surface to a paraboloid, coma is introduced. The effects of coma diminish in proportion to the square of the focal ratio and, for visual purposes, are of little consequence except close to the edge of the field of view in instruments with focal ratios of f:8 or more. Unless coma is corrected, its effects are very obvious in instruments with substantially shorter focal ratios and, in such cases, acceptable-quality images are restricted to the central part of the field of view. A parabolic mirror may be corrected for coma by placing a suitably shaped lens, or lenses (or mirrors), in front of its reflecting surface. Coma may be reduced in a compound lens by an appropriate selection of curvatures for its various surfaces.

Coma Berenices

(Berenice's Hair; abbrev. Com, gen. Comae Berenices; area 386 sq. deg.) A northern constellation which lies between Canes Venatici and Virgo, and culminates at midnight in early April. It is named after the lock of hair of Queen Berenice II of Egypt (*c*. 269–221 BC), which, according to legend, she gave to the gods for the safe return of her husband, Ptolemy III Euergetes, from battle. It was introduced by the Dutch cartographer Gerardus Mercator, who included it on a celestial globe in 1551.

A small, rather inconspicuous constellation, the brightest star in Coma Berenices is of magnitude 4.2. α Comae Berenices (Diadem) is an interesting close binary with pale yellow (F5) components, both of magnitude 5.2, separation ∼0–0.9″, period 25.8 years, the orbit lying almost edge-on, so the motion is practically along a straight line. Other interesting objects include Melotte 111, a wide (5°) open cluster of about 40 stars between fifth and tenth magnitude, M53 (NGC 5024), an eighth-magnitude globular cluster, M64 (NGC 4826, the Black-Eye Galaxy), a ninth-magnitude spiral galaxy, and NGC 4565, a tenth-magnitude edge-on spiral galaxy.

There are many galaxies in the southern part of Coma Berenices that belong to the great Virgo Cluster, and in the north-east of the constellation lies the distant Coma Cluster. The north galactic pole is also located in the constellation.

Coma Cluster

Coma, with Virgo, is one of the best-studied GALAXY CLUSTERS. The cluster is located at right ascension $12^h59^m48.7^s$, declination $+27^\circ58'50''$ (J2000) and lies almost at the north Galactic pole, $(l, b) = (58^\circ, +88^\circ)$. In the major catalog of galaxy clusters by Abell, its designation is Abell 1656 (see ABELL CLUSTERS). The mean redshift of the cluster is approximately 6900 km s^{-1}, which puts it at a distance of $69h^{-1}$ Mpc (where $H_0 = 100h$ km s^{-1} Mpc^{-1}). Coma is one of the richest nearby clusters, having 650 confirmed member galaxies and, including dwarfs, probably as many as 2000 galaxies in total. It has two central, dominant galaxies and therefore is classified as a binary cluster.

Coma has long been taken as the archetypal rich cluster. It appears regular and roughly spherical, with a strong central concentration. The spherical symmetry and general regularity meant that it was considered to be a good (if rare) example of a cluster that had achieved dynamical equilibrium and was therefore amenable to straightforward theoretical analysis. Work over the last two decades, however, has gradually revealed that Coma is far from relaxed, with many substructures. The complexity of the dynamical system reveals clues to the process of cluster formation.

The total mass of Coma has been estimated from observations of its gravitational effects on the galaxies and hot x-ray gas in the cluster. Assuming that the cluster is in dynamical equilibrium, the total mass is found to be much greater than the observed mass in the galaxies and x-ray gas. This result, first obtained by ZWICKY in 1933, remains one of the strongest pieces of evidence that the universe is predominantly composed of some form of unseen DARK MATTER.

History

William Herschel was the first to note the concentration of nebulae in the constellation COMA BERENICES in 1785 (see figure 1). The first catalog of 108 nebulae in Coma was given by Wolf in 1902 and expanded by Curtis to over 300 objects in 1918. The recession velocities for a few members of the cluster were measured by Hubble and Humason in 1931.

The place of the Coma cluster as a touchstone of extragalactic astronomy and cosmology was established when Zwicky derived an estimate for the mass of the cluster in 1933 and found it to be at least $2 \times 10^{14}h^{-1}M_\odot$, which was much greater than could be accounted for by the visible matter. This was the first evidence suggesting that some form of dark matter existed in the universe.

Cluster galaxies

Richness

Coma has 276 member galaxies brighter than $B = 18$ within $0.75h^{-1}$ Mpc (0.67°) of the cluster center and approximately 900 members brighter than $B = 20$ out to $1.5h^{-1}$ Mpc (1.33°). The distance modulus for Coma is $34.2-5\log h$, so that $B = 20$ corresponds to $M_B = -14.2$; about half the members of the Local Group of galaxies are dwarf galaxies with absolute magnitudes fainter than this, so the total number of galaxies in Coma is about 2000.

Luminosity function

The number of galaxies as a function of luminosity has been determined in Coma at optical, infrared, ultraviolet and radio wavelengths. The optical and near-infrared luminosity function (LF) is not very well fitted by the standard Schechter functional form and appears to have three main regimes: the number of galaxies per unity luminosity increases rapidly between the brightest cluster member at $B = 12.6$ and $B \approx 16$ ($L \approx 3 \times 10^9h^{-1}L_\odot$), and then levels off to $B \approx 18$ ($L \approx 0.5 \times 10^9h^{-1}L_\odot$), before increasing as a power law, $N(L) \propto L^\alpha$, for the dwarf galaxies at fainter magnitudes. The LF varies with position in the cluster. In the central regions the LF in fact has a peak at around $B \approx 16.5$ and a dip at $B \approx 17.5$ before rising steeply. This may be due to mass (luminosity) segregation as the cluster approaches equipartition of energy in the center, or due to increased merging in the cluster core or due to different evolutionary histories for the central galaxies. The steepness of the power law for dwarf galaxies also depends on position in the cluster, going from $\alpha \approx -1.3$ in the core to $\alpha \approx -1.8$ on the periphery.

Morphologies

As in most clusters, the galaxies in the core of Coma are mostly ellipticals and lenticulars, while the outskirts have a higher proportion of spirals. For the brightest 200 galaxies in the cluster, the mix is approximately E:S0:Sp = 30%:55%:15%. The variation in the morphological mix is reflected in the colors of the galaxies, with red galaxies dominating in the center and blue galaxies on the periphery. There is an excess of early-type galaxies in the region between the NGC4839 subcluster and the main cluster that show evidence of recent star formation, which may have been triggered by interaction with the tidal field of the cluster or the intracluster medium (ICM) as these objects fell into Coma. More generally, the E and S0 galaxies in the cluster are strongly concentrated along a northeast–southwest axis while the spirals show a more diffuse and isotropic distribution.

Dominant galaxies

There are three dominant (D or cD) galaxies in the Coma cluster. Two of these (NGC4874 and NGC4889) lie in the cluster core and cause it to be classified as a binary cluster (Bautz–Morgan class II). NGC4874 ($B = 12.8$) is a cD galaxy with an extended halo and an absolute luminosity of $5.8 \times 10^{10}h^{-1}L_\odot$ that is located close to the peak of the distributions of galaxies and x-ray gas. NGC4889, 0.12° east of NGC4874, is even brighter ($B = 12.6$, $6.9 \times 10^{10}h^{-1}L_\odot$), although it lacks an extended halo. Both NGC4874 and NGC4889 are estimated to have masses (within $80h^{-1}$ kpc) of $1.4 \times 10^{13}h^{-1}M_\odot$. NGC4874 is a strong radio source but NGC4889 is not. The third dominant

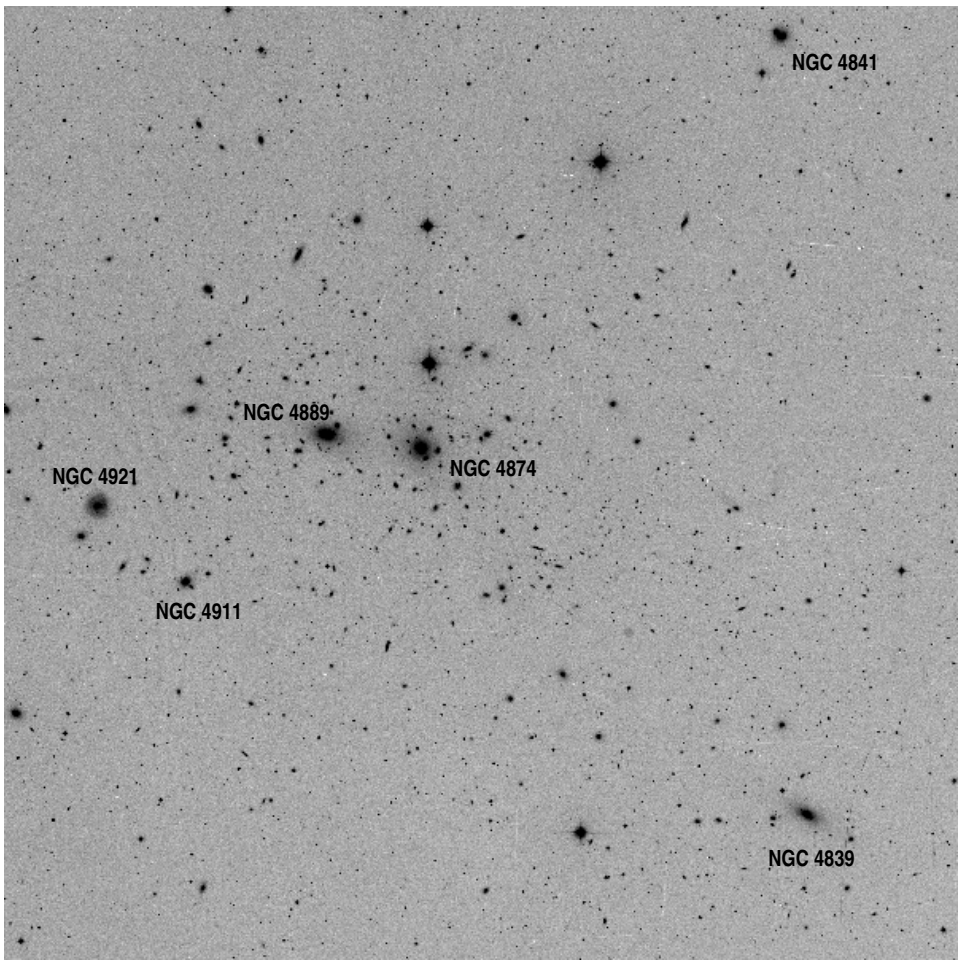

Figure 1. The visual appearance of the central region of the Coma cluster. This image, from the Palomar Observatory Sky Survey, is centered at $12^{\rm h}59^{\rm m}15^{\rm s} + 27^\circ55'00''$ (J2000) and covers $1.2^\circ \times 1.2^\circ$; north is at the top, east is at the left. It shows the core of the cluster around NGC4874 and NGC4889 and the southwestern group around NGC4839. (Credit: National Geographic Society, California Institute of Technology, Space Telescope Science Institute.)

galaxy is NGC4839 ($B = 13.5$), which lies well outside the cluster core, 0.67° away to the southwest of NGC4874. It is another cD galaxy, with luminosity $3.0 \times 10^{10} h^{-1} L_\odot$. It is also a head–tail radio source, with the tail pointing away from the cluster center. Each of the three dominant galaxies is the leading member of a subcluster within Coma (see below).

Dynamics

REDSHIFTS have been measured for 650 cluster members. The line-of-sight velocity distribution within the cluster can be resolved into two Maxwellian (Gaussian) distributions. One of these is the main body of the cluster, with a mean velocity of 6900 km s^{-1} and a one-dimensional velocity dispersion of 1100 km s^{-1}. The second is the group of galaxies around NGC4839, with a mean velocity of 7300 km s^{-1} and a dispersion of 300 km s^{-1}. The E and S0 galaxies which dominate the main cluster have a Maxwellian velocity distribution, indicating that they are approximately in dynamical equilibrium. However, the spiral galaxies in the cluster have a broader and flatter velocity distribution, which suggests that they are freely falling onto the cluster.

Intracluster medium

Coma has long been known to be a strong source of x-ray emission. The total x-ray luminosity of the cluster is approximately $2.5 \times 10^{44} h^{-2}$ erg s^{-1}. The x-ray emission comes from the ICM, a hot (8 keV $\approx 9 \times 10^7$ K) plasma with a mass at least as large as the mass in galaxies. Figure 2 shows the deepest x-ray image of the whole Coma cluster, taken with the ROSAT satellite. The cluster appears fairly regular apart from the obvious second peak in the x-ray emission centered on NGC4839, which has a luminosity of $10^{43} h^{-2}$ erg s^{-1}, typical of a bright group of galaxies. The temperature of this subcluster is higher than expected given its luminosity, suggesting that it has been shock-heated by its interaction with the cluster.

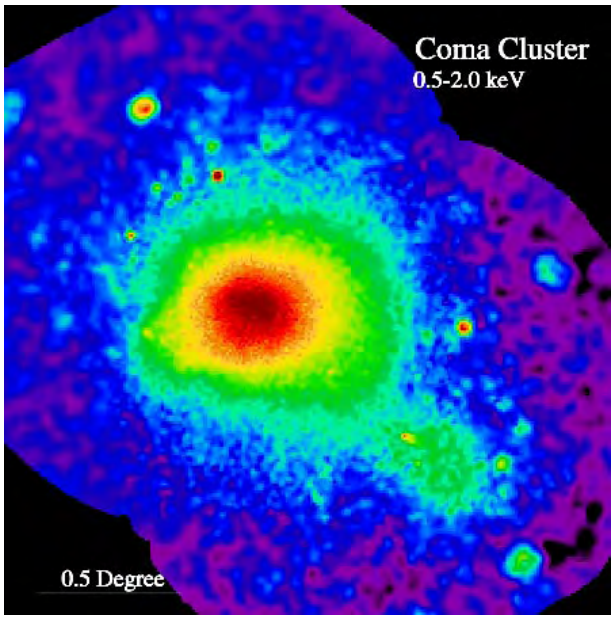

Figure 2. An x-ray image of the Coma cluster obtained with the ROSAT satellite, showing both the main cluster and the NGC4839 group to the south-west. (Credit: S L Snowden, High Energy Astrophysics Science Archive Research Center, NASA.)

Detailed analysis of the x-ray gas distribution shows that there is a double core in the cluster, with peaks associated with NGC4874 and NGC4889, surrounded by a more symmetrical diffuse component. The luminosity and temperature of the gas in these peaks are more consistent with a rich group or poor cluster than with individual galaxies. Unlike many other clusters, Coma does not possess a central cooling flow. This presumably is due to the disruption of the central regions associated with the interaction between the NGC4874 and NGC4889 subclusters. As well as the double core, there is also a distinct 'tail' of x-ray emission running outwards from the cluster center, passing through NGC4911 and ending near NGC4921. This feature has a luminosity of $10^{42}h^{-2}$ erg s^{-1} and an estimated gas mass of a few times $10^{11}h^{-1}M_{\odot}$. It may be associated either with another subcluster around NGC4911 or with the passage of the NGC4874 group through the cluster.

The temperature of the cluster generally decreases out from the center but also shows hot and cool regions. Initial maps of the x-ray gas temperature show evidence for variations associated with the substructures in the cluster. Mapping the temperature of the cluster with future x-ray satellites such as AXAF will greatly improve our understanding of the conditions in the ICM and the dynamics of the cluster. Images of the cluster in the extreme ultraviolet obtained with the EUVE satellite indicate that there is also a substantial amount of sub-10^6 K gas in Coma.

Coma is one of only 10 clusters possessing a diffuse radio halo (the 'Coma C' source); none of these clusters has a COOLING FLOW. This halo is probably produced by the *in situ* acceleration of relativistic electrons by a large-scale magnetic field. The conditions required to create a persistent cluster-wide radio halo have probably been produced by the on-going merger between the NGC4874 and NGC4889 subclusters, although the mechanism by which the kinetic energy of the merger is converted into radio emission remains unclear.

Structure

Detailed analysis of the distribution and dynamics of the galaxies and x-ray gas shows that there are at least four subclusters in Coma. The NGC4874 and NGC4889 subclusters are in the final stages of a merger at the core of the cluster, while the NGC4839 subcluster is either entering Coma for the first time from the direction of the nearby cluster Abell 1367 or is returning from that direction having already made its first passage through the cluster core. The fact that NGC4839 has a radio 'tail' pointing away from the main cluster indicates that the subcluster is inward bound and moving through a fairly dense ICM. Another subcluster has been identified around NGC4911, and there is some evidence for other, lower-level, structures.

There is a significant relation between structures on scales ranging from $10h^{-1}$ kpc up to $100h^{-1}$ Mpc. The major axes of the dominant galaxies and the distribution of E and S0 cluster galaxies and the x-ray gas are all approximately aligned with the filamentary structure (the 'GREAT WALL') running through Coma southwest to Abell 1367 at $cz = 6500$ km s^{-1} and northeast to Abell 2197/2199 at $cz = 9100$ km s^{-1}. The inference is that the cluster has been built up predominantly of material, both subclusters and individual galaxies, which have fallen in along this filament.

Mass and matter content

Ignoring the substructure and treating Coma as a spherical system with both the galaxies and x-ray gas in hydrostatic equilibrium, the total mass of the cluster is estimated to be $(3.1 \pm 0.5) \times 10^{14}h^{-1}M_{\odot}$ inside $1h^{-1}$ Mpc and $(6.5 \pm 2.5) \times 10^{14}h^{-1}M_{\odot}$ inside $3h^{-1}$ Mpc. Even within the limited context of these assumptions this is a wide range. For determinations of cluster mass using galaxy dynamics, this is partly due to the unknown anisotropy in the galaxy orbits (whether, at a given radius, the galaxies are predominantly on isotropic, radial or circular orbits); for determinations based on x-ray observations, the uncertainty lies in the unknown temperature distribution. As well, there is the unknown distribution of the dark matter which dominates the total mass of the cluster.

All current observations are consistent with a model in which 'light traces mass' (i.e. the dark matter has the same distribution as the visible matter), the galaxies are on isotropic orbits and the cluster has a uniform temperature. However, they are also consistent with models which depart significantly from this simplest case. The best-fitting models suggest that the ICM and galaxies have somewhat more extended distributions than the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

dark matter. The core assumption of all these models, namely that Coma is in hydrostatic equilibrium, is clearly violated at some level. The extent to which the observed substructure invalidates the conclusions of the equilibrium models is not yet clear, although early indications are that the mass estimates are reasonably accurate.

Zwicky's 1933 estimate of the V-band mass-to-light ratio (M/L) in the Coma cluster was about $100hM_\odot/L_\odot$; today's mass estimates correspond to values in the range 300–$400hM_\odot/L_\odot$. This exceeds M/L for individual galaxies by a factor of 10 or more, implying that there is of order 10 times as much mass in dark matter as there is in galaxies. However, the cluster M/L falls well short of the M/L of a critical-density ($\Omega = 1$) universe, for which $M/L \approx 1600hM_\odot/L_\odot$. The ratio of the luminous baryonic mass (i.e. the mass in galaxies and x-ray gas) to the total cluster mass is about 0.15 inside $1h^{-1}$ Mpc and 0.2–0.4 inside $3h^{-1}$ Mpc. This is considerably higher than the baryon fraction $\Omega_B h^2 = 0.012 \pm 0.002$ that is predicted by big bang nucleosynthesis for an $\Omega = 1$ universe (even for $h = 0.5$). Taken at face value, the mass-to-light ratio and baryon fraction of Coma both suggest a low-Ω universe.

Coma, Cometary

The roughly spherical, temporary atmosphere of gas and dust expelled from a comet's nucleus as a result of solar heating when the comet is sufficiently close to the Sun. The nucleus and coma are together known as the comet's *head*. The coma, which is typically drawn into a teardrop shape by the solar wind, contains neutral and ionized gas molecules which shine by fluorescence and reflected sunlight. The coma typically develops at 3–4 AU from the Sun and can grow to 10^5–10^6 km, reaching its maximum extent just after the comet's perihelion passage.

Combustion

The process whereby a substance is combined with oxygen with the production of heat. Burning is a familiar example of this process. The energy required to propel chemical rockets is provided by the combustion of fuel with an oxidant at very high temperatures. A common oxidant is liquid oxygen (often denoted by LOX). Others include hydrogen peroxide and nitrogen tetroxide.

Comet Arend–Roland (C/1956 R1)

A long-period comet discovered jointly by Sylvain Arend and Georges Roland in November 1956. It reached perihelion (0.32 AU) on 8 April 1957, and passed closest to Earth (0.57 AU) on 21 April. The comet attained a peak brightness of magnitude 0, and developed a dust tail that was 30º long at its greatest extent, but it was most notable for its antitail, which at best was half the length of the main tail and appeared as a pronounced spike extending from the head in the opposite direction to the tail. Anti-tails are an effect of perspective: when the Earth is close to the comet's orbital plane and the comet is heading in the general direction of the Earth, the curvature of the dust tail makes the tail visible on either side of the head. The inclination was 120º and the eccentricity given as 1, making the aphelion distance and period indeterminately large.

Comet Bennett (C/1969 Y1)

A long-period comet discovered by Jack Bennett in December 1969. It passed closest to Earth on 26 March 1970, having reached perihelion (0.54 AU) on 20 March, and was then at its brightest, at magnitude 0. The comet was best placed for observation in April, when its tail reached around 11°, some estimates putting it at 25°. Jets of material emitted by the nucleus spiraled out as the nucleus rotated. Bennett was one of the first comets for which a vast hydrogen cloud—surrounding the head at 13 million km, around 10 times the Sun's diameter—was detected, by ultraviolet observations made from Earth orbit. The eccentricity was 0.995, inclination 90°, period around 1700 years.

Comet Biela (3D/Biela)

A periodic comet that disintegrated in the nineteenth century and gave rise to the briefly active Bielid meteor shower; the 'D' in the prefix indicates 'defunct'. The comet was discovered in 1772 by Jacques Montaigne, and recovered by Jean-Louis Pons in 1805, but on neither occasion was it observed for long enough for an orbit to be computed. This was accomplished by Wilhelm von Biela when he recovered the comet in February 1826. He was able to follow it for 72 days, establishing its identity with the comets of 1772 and 1805, and it thus became the third known periodic comet. At its 1845/6 return the comet was observed to have split into two nuclei, one brighter than the other, separated by around 300 000 km. Both nuclei were seen to return separately in 1852, differing more in brightness and now over 2 million km apart. That was the comet's final apparition: there was no sign of either nucleus on what should have been the next favorable return in 1865/6, but in 1872 a meteor storm occurred, suggesting that the comet had completely disintegrated. There were further notable displays of what became known as the Bielid meteor shower at intervals corresponding to the comet's period of just over 6.6 years. The comet's disintegration into a meteor stream provided strong confirmation of the relationship between comets and meteors, first proposed by Giovanni Schiaparelli in 1866. At their final appearance, the twin nuclei (designated 3D-A and 3D-B) had inclination 13°, eccentricity 0.76 and period 6.62 years.

Comet de Chéseaux (C/1743 X1)

A long-period comet discovered by Dirk Klinkenberg on 9 December 1743, and independently by Philippe de Chéseaux four days later. It was also known as Klinkenberg's Comet, but it was de Chéseaux who computed its orbit and his name is now more commonly associated with it. This was one of the brightest comets of modern times, reaching an estimated magnitude -7 in February 1744. Its multiple tails—more than 10, according to some reports—formed a great fan that was visible in the pre-dawn sky before the comet itself rose. The comet reached perihelion (0.22 AU) on 1 March. Its inclination was 47°, and its eccentricity indistinguishable from 1.

Comet Donati (C/1858 L1)

A long-period comet discovered by Giovanni Donati in June 1858. It reached its greatest magnitude of −1 shortly before perihelion (0.58 AU) on 20 September, and was closest to Earth (0.5 AU) on 9 October. Its appearance was impressive, with a prominent curved dust tail stretching an estimated 60°, and two thin gas tails. Concentric, sharply defined shells of material ahead of the nucleus suggested that material was being ejected mainly from one vent when the rotation of the nucleus carried the vent round to the sunward side; the rotation period was estimated from the separation of the shells to be 4.6 h. The eccentricity was 0.996, the inclination 117°, and the period roughly 2000 years.

Comet Encke (2P/Encke)

The short-period comet with the shortest known period at around 3.3 years. It was discovered independently by Pierre Méchain in 1786, by Caroline Herschel in 1795, and by Jean-Louis Pons in 1805 and again in 1818. In 1821 Johann Encke calculated the orbit of Pons's 1818 comet and predicted its return to perihelion in 1821 to an accuracy of one day. Two years later he established this comet's identity with those observed in 1786, 1795 and 1805, and Encke's Comet, as it was known, thus became the second known periodic comet. Its early discovery and short period give it the record for the most observed returns to perihelion (0.33 AU), the 60th occurring in 2000. The comet seems to have been in a stable orbit for several thousand years, which poses the problem of why the historical record contains no sightings of it before 1786. The comet is now quite faint (sixth magnitude) and shows only a short tail, presumably having shed most of its dust and gas. However, at fourth magnitude it was a naked-eye object at several returns in the early nineteenth century. The orbit shows signs of slow decay, the present period being 3.28 years; its aphelion distance is 4.06 AU, the eccentricity is 0.85 and the inclination 12°. Debris from the comet forms a meteor stream which the Earth intersects twice a year, producing the Taurid shower in November and the daytime Beta Taurid shower in June.

Comet Family

A group of comets with broadly similar orbital elements. The distribution of aphelia of members of a comet group peaks at a value corresponding to the distance of a particular major planet from the Sun. Perturbations by that planet have been responsible for changing the diverse original orbits of the comets into those they now occupy. It was once thought that all the major planets possessed comet families. Only Jupiter's comet family is now recognized as real, those of Saturn, Uranus and Neptune being explained in terms of orbital resonances with Jupiter. Jupiter's comet family itself contains over two-thirds of all the comets officially designated as being of short period. An example of a comet recently captured by Jupiter into its family is 16P/Brooks 2, which in 1886 passed just two Jupiter radii from the planet, an encounter that changed its period from about 30 years to 7 years. The orbits of Jupiter's comet family are continually decaying, and members are eventually ejected from the solar system by a gravitational 'slingshot', or tidally disrupted. Fresh captures replenish the stock.

Comet Giacobini–Zinner (21P/Giacobini–Zinner)

A short-period comet discovered independently in 1900 by Michel Giacobini and in 1913 by Ernst Zinner. With a period of 6.61 years it is, like the majority of short-period comets, a member of Jupiter's comet family. It reached its greatest magnitude of 7 when it made its closest approach to Earth in 1946, passing at a distance of 0.26 AU. A brief outburst raised its magnitude to 6 for a few days, and similar short outbursts have been observed at other returns. These outbursts may be linked to storm-level activity in the comet's associated meteor shower, known as the Giacobinids, as occurred in 1946. The perihelion distance is 1.03 AU, aphelion distance 5.99 AU, eccentricity 0.71 and inclination 32°. In 1985 the comet became the first to be visited by a space probe when the International Cometary Explorer passed within 7800 km of its nucleus. A shock front was detected where the ionized species in the coma encountered the solar wind.

Comet Hale–Bopp (C/1995 O1)

Comet C/1995 O1 (Hale–Bopp) was discovered simultaneously by the two American amateur astronomers Alan Hale and Thomas Bopp on 23 July 1995. At that time, it was at 7.1 AU from the Sun and had already a total visual magnitude of 10, which is more than 100 times brighter than COMET HALLEY at the same distance. It passed perihelion on 1 April 1997, at 0.91 AU from the Sun. The orbit of comet Hale–Bopp is inclined by 89º over the ecliptic. Its orbital period was about 4200 yr before entering the inner solar system and changed to 2400 yr after gravitational perturbation by Jupiter. It is thus a long-period comet, presumably coming from the OORT CLOUD.

As soon as comet Hale–Bopp was discovered and its orbit determined, it was clear that it would be a very bright object at perihelion, one of the brightest ever recorded comets. Indeed, it reached a total visual magnitude of −1 around perihelion. With favorable viewing conditions, it was a naked-eye object in the northern hemisphere for more than 2 months. At that moment, its gas production reached 10^{31} water molecules s^{-1} (about 300 t s^{-1}, 10 times the rate of comet Halley). It may thus be counted as one of the 'Great comets' of our epoch.

The campaign of observations of comet Hale–Bopp

The early discovery of comet Hale–Bopp gave ample time to organize world-wide observations with major instruments. Comets Hyakutake and Hale–Bopp were the first comets of exceptional brightness (surpassing the apparitions of comet West in 1976 and P/Halley in 1986) to be observed with the powerful means of astronomy at the end of the 20th century: the versatile imaging possibilities of CCDs, the new spectroscopic ground-based facilities in the infrared, millimetric and submillimetric domains, and space observatories such as the Infrared Space Observatory (ISO), the Hubble Space Telescope (HST) and x-ray satellites (see COMET HYAKUTAKE for a discussion of x-ray observations of comets). It is thus not a surprise that a wealth of new results followed.

Coma dust patterns, nucleus rotation and size

A complex pattern of dust jets (up to seven) was seen in the inner coma (see COMA, COMETARY). These jets showed either spirals or a radial pattern, depending on the viewing geometry of the moment. Close to perihelion, a pattern of expanding shells was conspicuous even for observers with modest-size instruments. This phenomenon traces the unequal activity of the nucleus surface: 'active regions' are periodically exposed to solar heating as the comet nucleus is rotating. The observation of the time evolution of the jet (or shell) pattern allowed a period of 11.4 h for the rotation of the nucleus to be determined precisely and its axis to be assessed.

A nucleus diameter of 40–80 km was determined from observations with the Hubble Space Telescope, the Infrared Space Observatory and ground-based radiometry at millimetric wavelengths. This is the largest COMETARY NUCLEUS among those for which the size could be assessed (comet P/Halley had an elongated nucleus of 'only' 8 km × 8 km × 16 km).

The sodium tail

One of the highlights of the observations of comet Hale–Bopp was the detection of a third kind of COMETARY TAIL (in addition to the dust and ionic tails): a thin, straight tail revealed by the yellow D lines of atomic sodium at 589 nm, which shows up at an angle from the other straight ionic tail and distinct from the broad, curved dust tail. Emission of the sodium lines had already been observed in a number of comets, with hints for a sodium tail suggested in a couple of them, but this was the first time that the presence of the sodium tail was so conspicuous. The sodium D lines are emitted through fluorescence: photons from the Sun are absorbed and re-emitted isotropically; a transfer of momentum results, accelerating the sodium atoms away from the Sun at velocities which could exceed 80 km s^{-1}. The origin of the cometary sodium is ill understood. Decomposition of a gas-phase parent molecule seems to be ruled out. Sodium is rather released from cometary dust particles.

Evolution with heliocentric distance

The early detection of the comet allowed observers to study the evolution of this exceptional comet over a very large span of heliocentric distances and to see the 'turning on' of the sublimation of various molecules from the nucleus ices as the comet approached the Sun. Just after discovery, at 7 AU, carbon monoxide (at radio wavelengths) and the CN radical (in the visible spectrum) were already identified. Water (traced by the OH radical observed in the near UV or at radio wavelengths) showed up at only 4.8 AU. Cometary activity, which is driven by water ice sublimation at short heliocentric distances, is governed by the sublimation of more volatile species, especially carbon monoxide, at long distances. As the comet approached closer to the Sun, the apparitions of methanol (CH_3OH), hydrogen cyanide (HCN), hydrogen sulfide (H_2S), formaldehyde (H_2CO) and methyl cyanide (CH_3CN) were successively observed (see figure 5 of COMETARY ATMOSPHERES).

The same pattern was observed in reverse order as the various molecules 'turned off' when the comet receded from the Sun. In 2001, at about 14 AU from the Sun, comet Hale-Bopp is still observed to be active. Images obtained at the MPG/ESO 2.2 m telescope at La

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Silla still show the prominent, curved jet-like structure in the coma that was observed earlier, with a total size of the coma of around 2 million km. Carbon monoxide is also still strongly outgassed, as seen in radio spectroscopic observations at the SEST 15 m radio telescope, also at La Silla.

New molecules

An extensive spectroscopic investigation of comet Hale–Bopp at all wavelengths, using state-of-the art instruments, resulted in the detection of many new molecular species. Comet Hale–Bopp is thus now the comet for which the chemical composition is the best known (see COMETARY ATMOSPHERES). The list of cometary molecules is not closed, however, since many unidentified spectral features were observed.

The composition of volatiles in comet Hale–Bopp is found to be strikingly similar to the chemical abundances of interstellar ices (as recently observed with ISO) and to those observed in interstellar hot molecular cores and bipolar outflows around protostars.

Radio observations

In addition to the already-known cometary parent molecules (H_2O, CO, CO_2, CH_3OH, H_2CO, HCN, H_2S) and to the ones just discovered in comet Hyakutake (NH_3, HNCO, CH_3CN, HNC, OCS), several molecules were identified by radio spectroscopy (see figure 4 of COMETARY ATMOPHERES): the relatively complex organic molecules formic acid (HCOOH), acetaldehyde (CH_3CHO), methyl formate ($HCOOCH_3$) and formamide (NH_2CHO), the nitrile HC_3N, thioformaldehyde (H_2CS), all with abundances of the order of 10^{-4} relative to water. The sulfur oxides SO and SO_2 were observed with abundances of about 0.3%, making them an important sulfur repository. The NS radical was discovered, the origin of which (from the nucleus ices or from an unknown parent molecule) is still a puzzle.

Several ions were also observed for the first time by radio spectroscopy: CO^+, HCO^+, H_3O^+.

Deuterated water (HDO) was observed from one of its submillimetric transitions, with a D/H ratio of 3×10^{-4}, as in comets 1P/Halley and Hyakutake. The deuterated variety DCN of hydrogen cyanide was also observed with D/H of 2.5×10^{-3}. As discussed in COMET HYAKUTAKE, these values are intermediate between the cosmic D/H ratio and the ratios observed in interstellar molecules and provide a critical test for formation theories of the solar system.

Infrared observations

Ground-based spectroscopic observations in the infrared with the Cryogenic Echelle Spectrometer (CSHELL) on the NASA Infrared Telescope Facility (IRTF) in the 2.8–4.8 μm region allowed the observation of CO, CH_4, C_2H_2, C_2H_6, OCS, NH_3, of several radicals through their fundamental bands of vibration and of water through 'hot' bands which are not affected by telluric absorption.

The apparition of comet Hale–Bopp also coincided with the operation of the Infrared Space Observatory which could, for the first time, secure a cometary spectrum in the infrared range from 2.5 to 190 μm. The water molecule, which is so difficult to observe from the ground because of telluric absorption, could be observed in many details through its fundamental bands of vibration at 2.7 and 6.5 μm wavelengths and its rotational lines in the far infrared (180 μm). Carbon dioxide (CO_2) was observed through its vibrational band at 4.25 μm: this was the second comet in which this molecule (which cannot be investigated from the ground because of strong telluric absorption) was directly observed, after P/Halley where it was observed *in situ* with the infrared spectrometer aboard the VEGA probe. Its abundance was about 20% relative to water (at a distance of 2.9 AU from the Sun when the ISO observation was made), which makes it a major cometary volatile.

Distributed sources of molecules

Previous to observations of comet Hale–Bopp, it was already known that some 'parent' molecules were not coming from the sublimation of nucleus ices, but from a still ill-known 'distributed source' within the coma. This was demonstrated for CO and H_2CO by, e.g. *in situ* observations of P/Halley by the Giotto space probe.

Infrared long-slit spectroscopic observations of comet Hale–Bopp showed that CO was produced half from a distributed source and half from the nucleus when the comet was at less than 2 AU from the Sun. A distributed source for OCS was also found. The Institut de Radioastronomie Millimétrique (IRAM) interferometer on Plateau de Bure (France) and the Berkeley Illinois Maryland Array (BIMA) and the Owens Valley Radio Observatory (OVRO), both in California, could map at radio millimetric wavelengths the radio emission of some molecules, using a technique successfully applied before for comet Hyakutake. This allowed the space distributions of some species such as CO, H_2CO, SO, HNC, HCO^+ to be investigated and clues to their origin to be obtained.

The exact nature of these 'distributed sources' of molecules is still an enigma. It seems likely that they could be the organic grains observed *in situ* by the space probes which explored comet Halley (the so-called 'CHON particles'), but the desorption mechanism of molecules from these grains is still to be elucidated.

The HNC molecule (an unstable isomer of hydrogen cyanide HCN) was found to have an abundance ratio relative to HCN varying from 0.03 to more than 0.20 as the comet approached the Sun. This is not expected if HNC were well mixed with HCN in cometary ices. A possibility is that HCN is converted to HNC through charge-exchange chemical reactions within the coma, the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

reaction rates becoming more important when the density is higher, i.e. when the comet is more productive, closer to the Sun. Interferometric observations at IRAM indeed suggested that HNC has a distributed source.

Characterization of cometary dust

It was already known that cometary dust contained silicates from ground-based observations of their characteristic band around 10 μm and that part of them could be crystalline in some comets. The record of the full infrared spectrum of comet Hale–Bopp by ISO immediately revealed a series of additional spectral features at 16, 19.5, 23.5, 27.5 and 33.5 μm which were identified to be magnesium-rich olivine (forsterite Mg_2SiO_4), a special kind of silicate (see figure 6 of COMETARY ATMOSPHERES). A more quantitative analysis of the ground-based and ISO spectra of comet Hale–Bopp showed that its dust was essentially composed of forsterite, pyroxenes (another class of silicates such as $MgSiO_3$), amorphous silicates and spectrally featureless material which could be the organic-coated grains previously observed by the space probes which explored comet Halley.

The spectrum of comet Hale–Bopp in this spectral domain closely resembles that of the dust disks around some young or even evolved stars, such as that of HD 100546, an intermediate star between β Pictoris or Vega-like objects and Herbig Ae–Be stars, which were also observed by ISO. Thus, the dust contained in such disks appears to be similar to cometary dust.

In contrast, interstellar dust only shows silicates which are in the amorphous phase. Conversion of silicates from the amorphous to the crystalline phase, to our knowledge, can only occur through an annealing process at relatively high temperature (>1000 K). We still have to understand how comets such as Hale–Bopp could have incorporated apparently unprocessed interstellar volatiles on the one hand and evolved, crystalline silicates on the other hand.

Comet Halley (1P/Halley)

Comet Halley is probably the most famous comet on record. The reason is that it is the only bright comet, easily visible with the unaided eye, that comes back so often, namely with a periodicity that is never very different from 76 years. Since such a periodicity is roughly comparable to the duration of a human life, grandparents talk about it to their grandchildren and oral tradition has established its fame.

The 1682 passage of comet Halley

Until the 1682 passage of comet Halley, none of its previous passes had been identified as coming from the same object. At that time, no comet was known to be periodic, and the shape of the cometary trajectories was unknown. In particular, Johannes Kepler assumed them to be straight lines. However, a couple of years before the passage of comet Halley, Sir Isaac Newton established for the first time that a parabola fitted the observed trajectory of the Great Comet of 1680 much better than a straight line. A parabola was suggested as one of the possible solutions given by his new theory of universal gravitation.

In 1703, Isaac Newton's friend, EDMOND HALLEY, undertook to compute parabolic orbits for those 24 historical comets for which enough accurate data were available. Among the 24 parabolas, three of them were not only of the same size, but they were superimposed upon each other in space. Their dates of passage were separated by 75 and 76 years. He concluded that the three parabolas were actually the extremity of an extremely elongated ellipse. The three anonymous comets were therefore the three passages of the same single comet coming back periodically. Halley, rightly proud of his results, wrote (in Latin):

> *If, in agreement with our predictions, this comet comes back again in 1758, fair posterity will recognize that its return has been first predicted by an Englishman.*

The 1759 return

The comet was found back at Christmas 1758 by a German amateur; it passed at perihelion in March 1759. Since the return predicted by Halley had been verified, the so far anonymous comet was called for the first time Halley's comet or, by modern astronomers, comet Halley. Its 1758 passage played a pivotal role in continental Europe in convincing people that Newton's law of universal gravitation was correct. The reason is that Alexis Clairaut, using the existence of planetary perturbations to correct the comet's orbit for the first time, predicted the 1759 perihelion passage with an accuracy of one month.

The 1835 return

By comet Halley's 1835 return, improvements in optical instruments revealed for the first time the existence of physical phenomena taking place in the comet's head. In particular, Friedrich Bessel's drawings show jets, rays and fans that seem to be ejected sunwards before being repelled away from the Sun. Bessel interpreted his drawings by his now classical 'fountain model', already suggestive of vaporizing gases dragging dust away, sunwards off the nucleus. This looked like a confirmation of Laplace's ideas, written in 1803, about the existence of a solid frozen nucleus.

The 1910 return

Photography and spectroscopy brought a very large amount of data for the first time. In 1931, Bobrovnikoff published a major monograph of the 1910 passage, in which he used 709 photographs and several scores of spectrograms. The radicals and ions that had been identified in the heads and tails of former comets originated from only three elements: carbon, nitrogen and oxygen. Comet Halley's 1910 passage added hydrogen to this list (the Fortrat band of CH near 4300 Å). Bobrovnikoff assumed that the four identified elements (H, C, N, O) came from three 'parent' molecules vaporizing from the nucleus, namely carbon dioxide CO_2, ammonia NH_3 and water H_2O.

Fragmentation and ionization of these three molecules were able to explain all the observed spectra: CN, C_2, C_3, CH, OH, NH, NH_2, and the ions CH^+, OH^+, N_2^+, CO^+ and CO_2^+ (including later identifications). These data are the baseline upon which Fred Whipple would build his icy conglomerate model of the COMETARY NUCLEUS in 1950. The need for more parent molecules only became apparent later, because the absence of molecular collisions in most cometary coma was not observed previously.

The 1986 return: atomic abundances

With the help of space missions, comet Halley's 1986 passage brought a wealth of new data, coordinated by the International Halley Watch and preserved on compact disks in the Comet Halley Archives. The mean ratios in numbers of atoms of the light elements found in the volatile fraction of comet Halley were:

$$\mathrm{H/O} = 1.9 \pm 0.4$$

$$\mathrm{C/O} = 0.20 \pm 0.05$$

$$\mathrm{N/O} = 0.10 \pm 0.05$$

$$\mathrm{S/O} = 0.01 \pm 0.005.$$

The dust-to-gas mass ratio was found to be $M = 0.8 \pm 0.2$ for comet Halley. Its elemental abundances were found to be quasi-solar for the 17 elements measured, except for

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

hydrogen, which was depleted by a factor of about 500 in the comet with respect to the Sun. There was also a smaller discrepancy for Si, twice as abundant, and Fe, half as abundant in the comet as in the Sun, so that the ratio Fe/Si is four times smaller in comet Halley than in the Sun.

This anomalous ratio recalls the same type of anomaly in carbonaceous chondrites, where the Fe/Si ratio varies from 25% to 75% solar. COMETS and CHONDRITES are believed to have a similar origin, although a slightly different thermal history (chondrites were heated more than comets). The composition of the terrestrial planets also suggests that a variable iron deficiency exists in the inner solar system with respect to the Sun.

The 1986 return: molecular data

All chemical species identified in previous comets, plus a few more, were identified in comet Halley during its 1986 passage. They are listed in table 1.

The *mean* chemical composition of dust in comet Halley has also been established in percentages by mass. Dust contains 33% organics and 67% inorganics. The organic fraction is half unsaturated hydrocarbons and half more complex molecules also containing oxygen, nitrogen and sulfur. The inorganic fraction is three quarters silicates, the rest being FeS, graphite and sulfur; both fractions also contain bound water, probably hydration water.

The volatile fraction of comet Halley contained (in numbers of atoms) about 78.5% H_2O, 4.5% HCO–OH, 4.2% H_2CO, 3.5% CO_2, 1.0% CO; 2.5% N_2, 1.0% HCN, 0.8% NH_3, 0.8 N_2H_4, 0.4% $C_4H_4N_2$; 1.5% C_2H_2, 0.5% CH_4, 0.2% C_3H_2; 0.1% H_2S, 0.05% CS_2 and 0.05% S_2.

The composition of individual grains of dust from comet Halley has revealed a large dispersion of elemental abundances from grain to grain, although it seems possible to classify them into four distinct families:

Group A (carbon-rich) mean 54% C, 12% O, 10% metals (37 grains).
Group B (oxygen-rich) mean 54% O, 10% C, 15% metals (18 grains).
Group C (Mg–Si rich) mean 81% metals (but 5% Fe), 2% C, 2% O (10 grains).
Group D (iron-rich) mean 33% Fe, but 9% Mg, 5% Si, 8% C, 4% O (11 grains).

These submicroscopic grains seem to represent interstellar dust grains from four different sources, coming initially from different stellar environments, and which have never been thermally processed before sedimenting together to the mid-plane of the protosolar nebula, before accreting into comets.

Halo of vaporizing grains

The existence of an extended halo of vaporizing icy particles has been detected around the nucleus of comet Halley, in particular by its production of CO, probably coming from the photodissociation by the solar light of the molecules of formic acid HCO–OH and formaldehyde H_2CO, which have both been detected in the organic grains dubbed CHON by astronomers. Other icy grain halos had been detected before in other comets.

Isotopic ratios

Before comet Halley's 1986 passage, the only isotopic ratio measured in comets was the $^{12}C/^{13}C$ ratio measured from spectra of the C_2 radical. The spectra were difficult to measure because of the blend of the C_2 band with NH_2. Approximate ratios from 70 to 140 were assumed to be consistent with the terrestrial ratio of 89, rather than with the interstellar ratio of 43±4. However, the analysis of the ^{13}CN spectral lines in comet Halley gave an isotopic ratio of 65±9 for carbon in the CN radical. This isotopic ratio depends on the molecule considered because it comes from different fractionation effects. The interstellar ratio also varies from 40 to 90 in different molecules. The fact that some dust grains in comet Halley had different isotopic ratios for carbon can be interpreted as being due to the different origins of these grains in interstellar space, confirming the interpretation of their large dispersion in elemental abundances mentioned previously.

The D/H isotopic ratio has also been measured in comet Halley; first measurements had large error bars, but they have been considerably improved recently. Deuterium now yields 320 parts per million (ppm) in Halley's water, that is about twice as large as the concentration of deuterium in our oceans (about 156 ppm). This large deuterium enrichment has been confirmed in two recent bright comets (Hyakutake and

Hale–Bopp). Compared with the deuterium in the atmosphere of Jupiter, which represents a fair estimate of its content in the primeval nebular gas, the deuterium enrichment in the water molecules of comet Halley, as well as that in the two other bright comets, is by a factor of 16, whereas the enrichment in the water of our oceans is by a factor of eight.

Comet Halley's orbit

The present orbit of comet Halley is an extremely elongated orbit of eccentricity $e = 0.967$. With its 76-year period, its perihelion distance of 0.587 astronomical units (AU) sets its aphelion at almost 35 AU. Its inclination to the ecliptic is 17.8º but, because it orbits in a retrograde direction, its inclination is usually said to be 162.2º.

More than 30 of its previous passages have been computed backwards with an outstanding accuracy, which has allowed 30 passages to be retrieved unambiguously in historical documents. Its period has varied irregularly from 79.6 years (from 451 to 530 AD) to 74.4 years (from 1835 to 1910). The changes in its period come from the different positions of the giant planets, the attractions of which change its orbit slightly. In contrast, its orientation in space hardly changes.

The fate of comet Halley

All observed comets are short-lived because they come repeatedly into the inner solar system, where they decay in the solar heat; periodic comets usually disappear after two or three hundred passages. Comet Halley is no exception. Its frozen nucleus vaporizes gases that drag dust away; this produces those transient phenomena for which comets are so well known. Their heads and tails, constantly lost to space, are the best evidence of their decay. Such a decay often ends in a splitting of the nucleus. Eventually, all comets fade into invisibility. Minor fragments may remain forever along their orbits, or they may decay into finer and finer dust, if they do not eventually hit one of the planets.

Since we still see comets billions of years after the formation of the solar system, there must be a permanent source of new comets.

Sources of pristine comets

Indeed, *two* reservoirs of pristine comets have been found, where a large number of comets have remained since the origin of the solar system. One of them is the KUIPER BELT, a ring of millions of comets on quasicircular orbits beyond the orbit of Neptune; the other is the OORT CLOUD, a gigantic sphere centered on the Sun, the diameter of which is one thousand times the size of the planetary system; it contains billions of comets. These two reservoirs keep the comets in their pristine state in the deep cold of space.

The Kuiper Belt is somewhat perturbed by resonances with the orbit of Neptune; this produces the SHORT-PERIOD COMETS (periods between 3 and 30 years) whereas Galactic tides and sometimes the action of a passing star nearby perturb the Oort Cloud and produce the LONG-PERIOD COMETS (periods more than 200 years).

Comet Halley is a special case: with only a few other comets, its period lies in the gap between short- and long-period comets; for this reason, it should probably be called an 'intermediate-period' comet. Consequently, its origin is not completely certain.

Origin of comet Halley

The very fact that comet Halley is on a retrograde orbit makes it more probable that it was captured from the Oort Cloud. The reason is that all Kuiper Belt comets turn in the prograde direction, as do all the planets. A close encounter with a planet, which would have switched its direction drastically, is a highly improbable event. If comet Halley came from the Oort Cloud some millennia ago, then it shared a common origin with all the other comets of this cloud. The Oort Cloud was formed during the accretion of the giant planets. The growth of these very massive objects ejected a large fraction of the icy PLANETESIMALS that formed in their zones, into the Oort cloud. Uranus and Neptune were the most effective; Jupiter and Saturn became too massive and developed a gravitational field that ejected most of the icy bodies too far away into space to be kept by the Sun's gravitation inside the Oort Cloud.

So the ultimate origin of comet Halley lies probably among the icy planetesimals that accreted in the zones of Uranus and Neptune. The numerous isotopic anomalies mentioned before in the dust grains of comet Halley confirm that the interstellar grains that accreted into such an icy planetesimal had never been heated before; if it had been formed in the zone of Jupiter, the larger temperature of the PROTOPLANETARY DISK (near 220 K) would have induced neutral isotopic-exchange reactions with the nebular hydrogen, which would have also diminished the deuterium enrichment of its water, from 16 down to 6. Since this was not the case, this seems to be the best proof of the ultimate origin of comet Halley. Its deuterium enrichment corresponds to unmodified interstellar conditions. In the outer solar system, it was too cold for neutral isotopic-exchange reactions to work.

The nucleus of comet Halley

Although very small, the cometary nucleus is the only permanent feature of a comet. Head and tail are transient phenomena that appear only near the Sun. They are remnants of the decay of the nucleus into dust and gas. It was known by indirect means that cometary nuclei were objects of a few to a few tens of kilometers, but the nucleus of comet Halley is the first nucleus that has been photographed from nearby (figure 1). This was done in 1986 during the flyby of the GIOTTO spacecraft (European Space Agency).

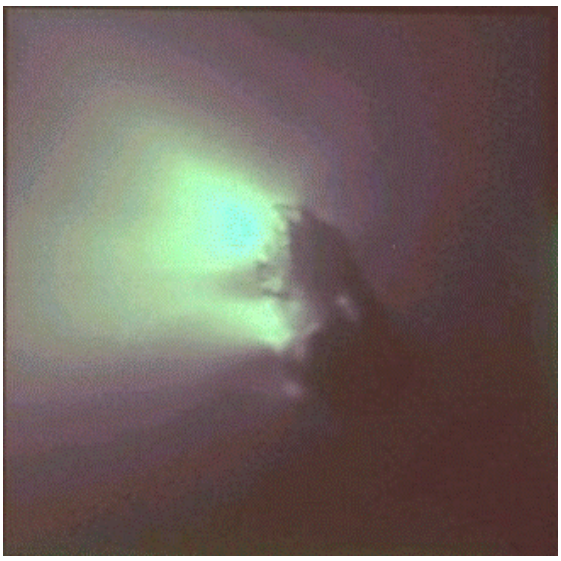

Figure 1. Comet Halley's nucleus, seen from a distance of 4000 kilometers by the Giotto spacecraft during its close passage on 13–14 March 1986. The nucleus is black and irregular; its vents eject gas and dust to the left.

The pictures revealed that it was quite irregular in shape; 90% of its surface area is covered by a black crust that is assumed to be made of silicate grains glued with black organic material looking like soot and clearly containing a large amount of carbon. The loss of water ice and more volatile ices in the crust does not extend very deep; the crust is pierced with many openings that act as erupting craters or fountains from which the inside snows vaporize. What we see now is clearly the result of many passages close to the Sun, where the surface of the nucleus was heated enough to lose its volatiles and weld its grains together. However, the heat conduction of the crust allows the nearby layers of volatiles to vaporize during each passage to perihelion, and their pressure has to become large enough to keep open many 'fountains', which feed the coma and the tails, until the comet has cooled down enough by receding from the solar heat. The nucleus of comet Halley is an elongated body measuring about 8 by 15 km, which seems to have resulted from two roughly spherical icy planetesimals that stuck together.

Comet Halley's 1986 passage has played an important role in clarifying many features and properties of comets, including their origin. It now seems rather well established that cometary nuclei have been accreted from icy interstellar grains that had sedimented first into the mid-plane of the protosolar nebula. The still existing comets are more or less pristine remnants of the stuff which was not used to make the planets.

Bibliography

More information about the remarkable co-ordination between amateur and professional astronomers under the name of the 'International Halley Watch' (IHW), at the occasion of the 1986 passage of Comet Halley can be found in the publication detailed below. This organization was sponsored by the International Astronomical Union and supported by NASA.

Comet Hyakutake (C/1996 B2)

Comet C/1996 B2 (Hyakutake) was discovered on 30 January 1996 by the Japanese amateur astronomer Yuji Hyakutake. (It should not to be mistaken for another 'comet Hyakutake' discovered by the same person 5 weeks before, C/1995 Y1, which was much less spectacular.) It was soon found out that comet Hyakutake was to make a close approach to Earth on 25 March 1996, at only 0.102 AU (15 300 000 km). It passed perihelion on 1 May 1996 at 0.230 AU from the Sun. This body is a long-period comet (about 9000 yr) with an orbital plane inclined by 125º over the ecliptic; it is presumably coming from the OORT CLOUD.

Close approaches of comets to Earth

Several COMETS are known to have passed peculiarly close to the Earth. Among those with well-known orbits, the closest approach was made by comet D/1770 L1 (Lexell) in 1770: only 0.015 AU (i.e. 2 400 000 km, seven times the Moon-to-Earth distance). In the 20th century, 7P/Pons–Winnecke passed at 0.039 AU in 1927, 73P/Schwassmann–Wachmann 3 at 0.062 AU in 1930 and C/1983 H1 (IRAS–Araki–Alcock) at 0.031 AU and C/1983 J1 (Sugano–Saigusa–Fujikawa) at 0.063 AU in 1983. The close approach of comet Hyakutake at 0.102 AU is thus rare but not exceptional. This comet, however, was a relatively highly productive one, which expelled about 2×10^{29} water molecules s^{-1} (about 5 t s^{-1}) when it was at about 1 AU from the Sun: this is no less than 1/5 of the production of COMET HALLEY at the same distance. This made the comet a very bright object at the end of March 1996, reaching a zero total visual magnitude when at its brightest. It was a conspicuous naked-eye object for several days with a tail extending up to 90º.

The campaign of observation of comet Hyakutake

A campaign of observation, mustering most large astronomical instruments, had to be organized at short notice. It collected many new results on cometary science, just before the equally successful observations of comet C/1995 O1 (Hale–Bopp).

The nucleus, size and rotation

A radar echo could be obtained from the comet using the 70 m Goldstone antenna in California. Since the radar signal is proportional to Δ^{-4} (Δ being the distance of the observer to the target), only comets at a close distance could be observed, and, until now, only a handful of them could be detected by radar techniques: 2P/Encke, 26P/Grigg–Skjellerup, C/1983 H1 (IRAS–Araki–Alcock) and 1P/Halley. From these observations, the COMETARY NUCLEUS of comet Hyakutake was found to be 2–3 km in diameter. Compared with the high level of activity of the comet, this small size indicates that most of the surface is covered with exposed, sublimating ice. Despite the small distance to the observers, the nucleus was too small to be resolved by optical means.

The rotation period of the comet nucleus was determined to be about 6.3 h from near-nucleus imaging and from the comet's light curve.

Several secondary nuclei were observed from images taken just after the close approach to Earth of the comet. Each fragment was surrounded by its own coma. They receded in the anti-solar direction with a velocity of about 12 m s^{-1} and progressively disappeared. Obviously, they were not due to a major break-up of the nucleus, such as those which occurred to comets C/1975 V1 (West) or D/Shoemaker–Levy 9, but rather to fragments of the external crust of the nucleus torn off by cometary activity. It is probable that such a phenomenon is common among active comets but can only be observed at the favor of a close approach.

New molecules

Before the observations of comet Hyakutake, only a handful of parent molecules had been firmly identified in comets: H_2O, CO, CO_2, CH_3OH, H_2CO, HCN, H_2S. Spectroscopic observations, mainly in the radio and infrared domains, allowed the identification of many more species (see also COMETARY ATMOSPHERES.

Ammonia (NH_3), suspected to be the progenitor of the NH and NH_2 radicals, was observed through its centimetric lines with an abundance with respect to water of about 0.7%. This makes this molecule the main repository of cometary nitrogen. Other nitrogen compounds were observed as minor species by their millimetric radio lines: isocyanic acid (HNCO), methyl cyanide (CH_3CN) and hydrogen isocyanide (HNC, an isomer of hydrogen cyanide HCN unstable in the conditions of terrestrial laboratories). A sulfuretted molecule, carbonyl sulfide (OCS), was also detected by radio spectroscopy.

Deuterated water (HDO) was observed by its radio line at 465 GHz. The corresponding [D]/[H] ratio is 3×10^{-4}, a value close to that observed by the mass spectrometers of Giotto during their flyby of comet Halley. This value shows an enrichment of about a factor of 10 over the 'cosmic' abundance of deuterium in the primitive solar nebula ([D]/[H] = 2.5×10^{-5}), where deuterium was mainly contained in the HD molecule. It is not, however, as large as that observed in some interstellar molecules ([D]/[H] = several 10^{-3}). Deuterium enrichment can naturally result from cold-temperature chemical reactions, such as those which occur in the interstellar medium. The enrichment observed in comets suggests that deuterium was not re-equilibrated in cometary water and that cometary material retained, at least partly, the signature of interstellar matter.

The apparition of comet Hyakutake also gave the opportunity to make the first successful interferometric observations of a comet at millimetric wavelengths, soon assessed by further observations of COMET HALE–BOPP.

Infrared observations used a new generation of high-resolution, sensitive spectrometers such as the Cryogenic Echelle Spectrometer (CSHELL) on the NASA Infrared Telescope Facility (IRTF). CO and HCN were observed for the first time in the infrared, and several hydrocarbons were revealed. Methane (CH_4), suspected for a long time to be the parent molecule responsible for the presence of the CH radical, but never yet firmly identified, was observed with an abundance of about 1% relative to water. Ethane (C_2H_6) was also observed with almost the same abundance, as well as acetylene (C_2H_2), which is an unsaturated hydrocarbon (see figure 3 of COMETARY ATMOSPHERES). The presence of both saturated and unsaturated hydrocarbons shows that cometary molecules are not the result of equilibrium chemistry. Carbonyl sulfide (OCS) was also detected in the infrared.

Ultraviolet observations with the Hubble Space Telescope revealed the S_2 molecule, seen for the second time in a comet, the first one being C/1983 H1 (IRAS–Araki–Alcock) at its very close approach to Earth. Obviously, this molecule which has a very short lifetime can only be detected by high spatial resolution observations of close comets. How this molecule could be incorporated in cometary matter, or created by chemical processing of cometary ices or within the inner coma, is not yet understood.

X-ray observations

A totally unexpected result was the detection of x-ray emission from comet Hyakutake. This results from the use of three x-ray satellite observatories, initially dedicated to the observation of high-energy emissions from the Sun or galactic and extragalactic sources: the Röntgen X-ray Satellite (ROSAT) which made the initial detection of the comet, the Rossi X-ray Timing Explorer (XTE) and the Extreme Ultraviolet Explorer satellite (EUVE; see figure 2(a) of X-RAY ASTRONOMY). This discovery was soon confirmed in comet Hale–Bopp, and the emission of several other comets could also be retrieved from the archive data of x-ray satellites. This phenomenon is therefore not rare and could be observed even in some faint comets. It opens quite a new prospect for cometary observations and its interpretation is a new challenge for cometary physics.

High-energy radiation such as x-rays cannot be emitted by a comet on its own, which is an inert, cold body. Rather, this emission comes from the interaction of cometary matter with high-energy solar radiation or solar particles. The exact nature of this interaction has been elucidated recently by a reexamination of the EUVE data on comet Hyakutake and from independent observations of comet C/1999 S4 (LINEAR) by the Chandra X-ray Observatory, which show emission lines of highly excited ions. Charge transfer from heavy ions in the solar wind to neutral atoms in the cometary atmosphere excites cometary atoms to high electronic levels, and their de-excitation results in x-ray emission. This rules out other proposed mechanisms such as scattering of solar x-ray emission by very small (attogram) cometary grains.

Comet Ikeya-Seki (C/1965 S1)

Among the small bodies of the solar system, comet Ikeya-Seki—the Great Comet of 1965—is an outstanding object for more than one reason. It belongs to an exceptional class of comets, the Kreutz sungrazing group, an ensemble so called because its members have extremely small closest approach distances, thus brushing the Sun at perihelion (see COMETS: KREUTZ SUNGRAZING). Ikeya-Seki is one of the brightest members of the family, certainly the most brilliant and best observed in our epoch. In close proximity to the Sun, part of the refractory component of the cometary material (the 'dust') is vaporized owing to the very intense heat so that heavy, metallic elements, which are not seen at larger distances, are set free and can be detected. Numerous emissions due to such elements were indeed photographed and identified in detail for the first time in the optical spectra of Comet Ikeya-Seki. Similarly, it was on this comet that the first infrared multiband observations were made and used to derive some further information on the cometary dust. Ikeya-Seki will also be remembered as one of the most spectacular comets of this century, with one near the beginning (the Great Daylight Comet of January 1910) and another close to the end (Hale–Bopp, the Great Comet of 1997); these two latter comets were not Kreutz sungrazers, but they were quite intrinsically bright, especially COMET HALE-BOPP.

Discovery: designations

Comet Ikeya-Seki was discovered on 18 September 1965, independently by two Japanese amateur astronomers, Kaoru Ikeya and Tsutomu Seki. Thus it bears the names of two very strenuous and successful 'comet hunters' who systematically and patiently scrutinize the sky on every clear night in search of new fuzzy moving objects. To the name is added a year designation. Thus, this comet is known in the literature as Ikeya-Seki (1965f) or (1965 VIII). According to a new system adopted recently it is also designated as C/1965 S1 (Ikeya-Seki).

Our famous comet, it should be noted, must not be confused with another Ikeya-Seki discovered about two years later, 1967n=1968 I=C/1967 Y1.

The orbit: a sign of parentage

Only a few days after the discovery, it was realized that the comet would pass very near to the Sun and when, a little later, enough observations had been secured for a reliable trajectory to be determined, the orbital elements left no doubt: in fact, a new member of the sungrazer family was coming in. It was actually the eighth member to be rather well known at that time. All these objects approach the inner solar system from almost exactly the same direction in space and they follow very nearly identical paths, the principal difference being in the period of revolution (500–1100 years, for those that are known), hence in the timing of their appearance.

The idea that some comets form a group or family means that a physical or genetic relationship is thought to exist among these individual objects. This concept as applied to a number of comets with very similar orbits and extraordinarily small perihelion distances dates back to the end of the nineteenth century. KIRKWOOD, and after him Kreutz, who first studied in great detail the orbits of sungrazing comets, contended that these comets were formed by the disintegration of an ancient, giant parent comet. The sungrazer family has been discussed further in the twentieth century, particularly by Marsden and by Öpik, after the passage of Comet Ikeya-Seki. More recently, Bailey and his collaborators have proposed that long-term secular gravitational perturbations in the solar system produce gradual changes in the orbital elements of some comets, leading to sungrazing trajectories; they suggest that such transformations into a sungrazing phase are not infrequent in the dynamical evolution of long-period comets. Let us mention briefly here a special parental link between two members of the family: the orbital elements of comet Ikeya-Seki bear so close a resemblance to those of the Great September Comet of 1882 (1882 II or C/1882 R1), for example their perihelion distances differ by only 0.000 04 AU (1 AU, one astronomical unit, is the mean distance from the Earth to the Sun), less than 1% of the solar radius, that these comets were probably born together when their direct parent split at perihelion (this may be the Great Comet of 1106, as indicated by Marsden). Thus, 1882 II and 1965 VIII are twin sisters—not identical twins, however, since the former was appreciably bigger and brighter than the latter.

The orbit of Ikeya-Seki itself is shown schematically in figure 1. It is an extremely elongated ellipse which takes the comet right through the solar corona at perihelion: it is then at a distance from the Sun's surface of only two-thirds of the solar radius, that is a little less than 500 000 km, whereas at the other end of the orbit (at aphelion) it is about 30 billion kilometers away. A sungrazing comet typically pays us but a lightning visit and provides a striking example of Kepler's second law, according to which the line between the Sun and the orbiting body (the radius vector) sweeps over equal areas in equal intervals of time (see KEPLER'S LAWS). Thus, Ikeya-Seki swung through one-half turn around the Sun in less than four hours (its velocity at perihelion was 480 km s^{-1}), whereas it takes some 900 years for it to make a complete revolution!

From the brightness of the comet at discovery and shortly thereafter, it was foreseen, and widely announced, that Ikeya-Seki would be an impressive sight when close to the Sun. Spectacular it was indeed (figure 2) reaching

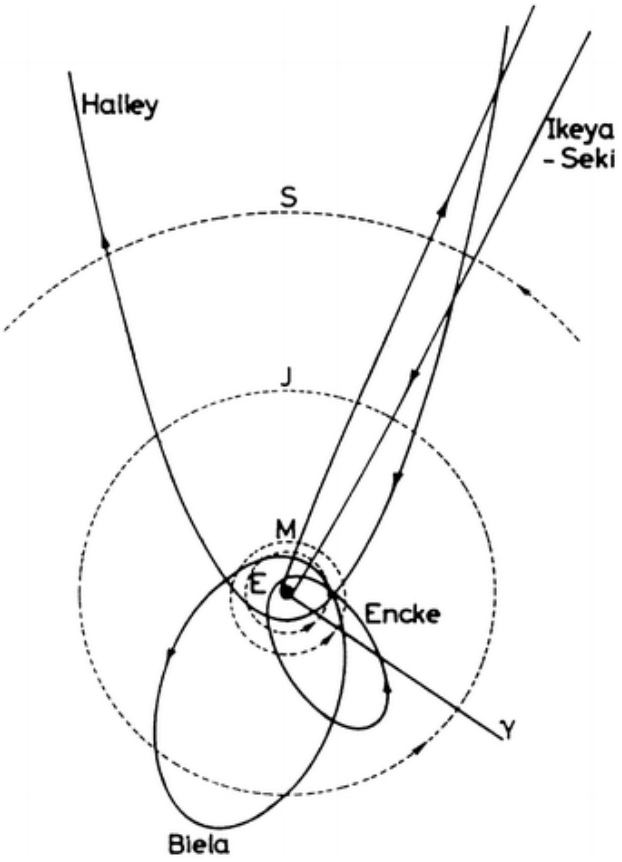

Figure 1. Orbits of Comet Ikeya-Seki (1965 VIII or C/1965 S1) and some other famous comets represented in a simplified manner, in projection onto the plane of the ecliptic (orbital plane of the Earth); also shown for comparison, as dotted lines, are the orbits of a few planets (Earth, Mars, Jupiter and Saturn). The orbit of Ikeya-Seki is a highly eccentric ('plunging') ellipse, close to a parabola. At perihelion the comet truly skims over—'grazes'—the Sun, flying at a distance from the center of the star of only 1.67 times its radius. This exceptionally small perihelion distance, less than one-hundredth of an astronomical unit (AU), could not be shown on the scale of the figure. On the other hand, the aphelion, almost 200 AU away, is out of scale, well outside the planetary system. On this scale again, the orbits of the other members of the sungrazer family to which Comet Ikeya-Seki belongs could not be distinguished from this comet's trajectory. The orbit in space is tilted 38º to the ecliptic; the orbital element 'inclination' taken as 142º indicates that the orbit is retrograde, like that of Comet Halley, which means that the motion is clockwise as seen from the north celestial pole, as opposed to the prograde motion of the planets and of the other two comets. Because the major part of their orbit lies south of the ecliptic, the sungrazing comets are not easy objects for observers in northern latitudes.

an astronomical magnitude of about −10 to −11 at its brightest (i.e. comparable in brightness to the Moon, somewhere between quarter-phase and full moon, or several hundred times brighter than Venus at greatest brillancy) and exhibiting a splendid tail (sometimes 30º

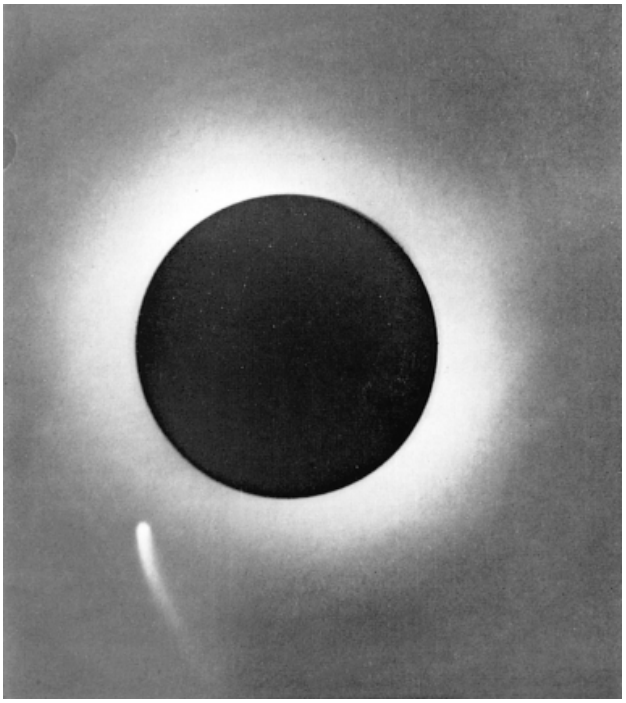

Figure 2. Photograph of Comet Ikeya-Seki obtained two hours before its perihelion passage on 21 October 1965. North is up, east to the left. The Sun is occulted by a black disk surrounded here by scattered solar light (not due to the corona). The swift, accelerated (northeasterly) motion of the comet causes the tail particles to lag far behind the radius vector sun-comet. (Photograph obtained at the Norikura Corona Station of the Tokyo Astronomical Observatory. Reproduced from Hirayama T and Moriyama F 1966 Observations of comet Ikeya-Seki (1965f) *Publ. Astron. Soc. Japan* **17** 433–6.)

long) for a few weeks around perihelion (figure 3). Unfortunately, however, the shape and orientation of the orbit of a sungrazer render its observation rather difficult. So, owing to the small angular distance of Comet Ikeya-Seki to the Sun and its position in the sky, always south of the celestial equator, the magnificent show it gave was reserved essentially for amateur and professional astronomers in privileged sites with very clear skies, at not too large geographical latitudes. It was well observed in Japan, Australia and New Zealand, South Africa, southern Europe, South America, Mexico and in the southwestern part of the United States. Like many other sungrazers, Ikeya-Seki faded away quite rapidly; it was observed for less than four months after perihelion.

Physical characteristics: size, structure

Fragmentation is a common occurrence amongst sungrazers. For example, comet 1882 II was observed to have broken up into more than five pieces near perihelion; similarly, several reports indicated that at least three subnuclei (one much brighter than the others) appeared right after Ikeya-Seki's closest approach to the

Figure 3. This picture was taken on 29 October 1965, when Comet Ikeya-Seki was 0.45 AU (67 million km) from the Sun and 1.05 AU (157 million km) from the Earth. The tail extends over a little more than 30º, corresponding to a total length of almost 90 million km (true length corrected for projection effect). Notice the presence of structure in the tail. The wavy or helicoidal pattern in the distant part of the tail may be due to the electromagnetic interaction of very small electrically charged cometary grains with the solar wind, as suggested by Horanyi and Mendis. (Photograph by E A Harlan, at the Lick Observatory, Mount Hamilton, California. Reproduced from Heck A 1985 Astronomes amateurs et observations cométaires *Ciel et Terre, Bull. Soc. Roy. Belge d'Astron.* **101** 115–20.)

Sun. Sungrazing objects are formed, we believe, by a multistep process which starts with the breaking apart of the progenitor, many centuries or millennia previously, followed by the disruption of the successive descendants when they return to the Sun's neighborhood. This most probably produces a very large number of small sungrazers, a notion supported by the current discovery of more and more such 'pygmy' sungrazers (in J E Bortle's phrase) with the coronagraphs aboard the Solar and Heliospheric Observatory (SOHO).

The question which comes to mind when a sungrazing comet is seen before perihelion is indeed will it survive? In short, the answer is the bigger fellows will (even if fractured), the pygmies will not. Size and internal strength are the determining factors for avoiding breakup or complete dissipation. As they pass so close to the solar furnace, these comets are subjected to very intense thermal stresses and a more or less important fraction of their mass will be vaporized. Besides, they experience another physical influence from the Sun, a tidal effect. Since the central gravitational attraction is inversely proportional to the square of the distance, the action of the Sun is stronger on the parts of a passing body closest to it than on the most distant parts. This difference may be significant if the solid body is larger than a certain critical limit and is in addition not sufficiently strongly structured, it will then not be able to resist the differential gravitational force and it will split or break up: this is called tidal disruption.

On the basis of dynamical, evolutionary and statistical arguments and using observational data pertaining to the best known sungrazers, Ikeya-Seki in particular, several astronomers have been able to draw inferences regarding the origin and the orbital stability of this class of comets, as well as on some of their physical properties. Consider, for instance, the differential velocities acquired by the fragments of a sungrazer after perihelion passage. If, as Öpik did, we ascribe these differences to differences in the radial deceleration or 'rocket effect' produced on the subnuclei of different sizes as they eject gases in a general sunward direction, we can estimate the dimensions of these various fragments. Applying this method to Ikeya-Seki and using the observed successive separations of the two main companions, one determines that the brighter of these had a diameter between 5 and 10 km, the fainter one being about twice as small. These dimensions are compatible with the lower limit obtained by Sekanina for the diameter of the parent nucleus (3–5 km) on the basis of a different assumption, namely that the relative motions of the subnuclei are attributable to the separation velocity imparted at breakup (this is identified with the equatorial rotational velocity of the parent comet, rotation also being a possible contributing cause to disruption). With an assumed density of 1 g cm^{-3}, the mass of Comet Ikeya-Seki may have been of the order of 10^{14} kg (some five times less than the mass of COMET HALLEY). The mass of the twin sister 1882 II was probably 100 times greater, that of the 'gigantic' ancestor of the sungrazers some two orders of magnitude higher still, i.e. a mass of say 10^{18} kg. This huge number must be put in an astronomical perspective: it represents but a mere one-ten-millionth or so of the Earth's mass!

Since cohesive strength and size are closely related in tidal breakup, knowledge of the latter (at a given distance from the central body) can be used to derive some information regarding the former. Even though the inferred values are approximate, they are rather instructive. By means of a simplified model (non-rotating, homogeneous, spherical nucleus), applied to the data available for Ikeya-Seki and some other members of its family, Öpik showed that the forces of cohesion which

Dirac House, Temple Back, Bristol, BS1 6BE, UK

hold these bodies together are much weaker than those of any known relevant materials (like terrestrial rocks or the parents of meteorites), except meteoric 'dust balls' (loosely bound assemblages of dust grains observed as meteors when they enter our atmosphere), which are characterized by crushing strengths of the order of 10^4 dyn cm^{-2}, about four (respectively five) orders of magnitude lower than the tensile (respectively compressive) strengths of rocks. These findings are generally consistent with WHIPPLE's comet model which describes the nucleus as a loose, porous aggregate of icy and mineral matter. Low cohesive strength is also in accord with the fact that fragmentation of comets is often observed to occur even at large distance from a massive body like the Sun or Jupiter, hence in the absence of any tidal action. Finally, it is worth recalling that although rather fragile, cometary nuclei are nevertheless resistant enough to survive a grazing approach to the Sun, the larger ones in any case being observed in the form of several persistent components after their splitting experience.

Clues on the nature and composition of cometary dust

In spite of the great difficulties involved in observing an object located only a few degrees away from the Sun in the sky, considerable efforts were devoted to obtaining data on Comet Ikeya-Seki around perihelion, particularly spectroscopic data. The strong incentive arose from the fact that this sungrazer was offering a very rare—so far unique—opportunity to get direct evidence on the composition of cometary dust by remote observations. Our very limited knowledge of the relative abundances of the heavy elements in comets otherwise comes essentially from the study of meteoroids of cometary origin or from *in situ* measurements (possible only in Halley's comet until now). Thus, quite a number of spectra of Ikeya-Seki were secured on 20 and 21 October 1965, at several observatories (Ratcliffe, South Africa; Sacramento Peak, New Mexico; Lick, California; Kitt Peak, Arizona; Haute-Provence, France).

The evaporation (or rather sublimation) of the non-volatile substances which constitute the cometary dust requires relatively high temperatures, above approximately 1000 K, reached only when a comet is sufficiently near to the Sun. Huebner has studied the sublimation of refractory components by the solar radiation and determined the vaporization rate and lifetime of dust particles as a function of their size, of the latent heat of their constituent materials and of the heliocentric distance (r). It is clear that the metallic elements which are chemically bound in the 'rocky' material, in the form of silicates or oxides can only be liberated when r is less than 0.1–0.2 AU.

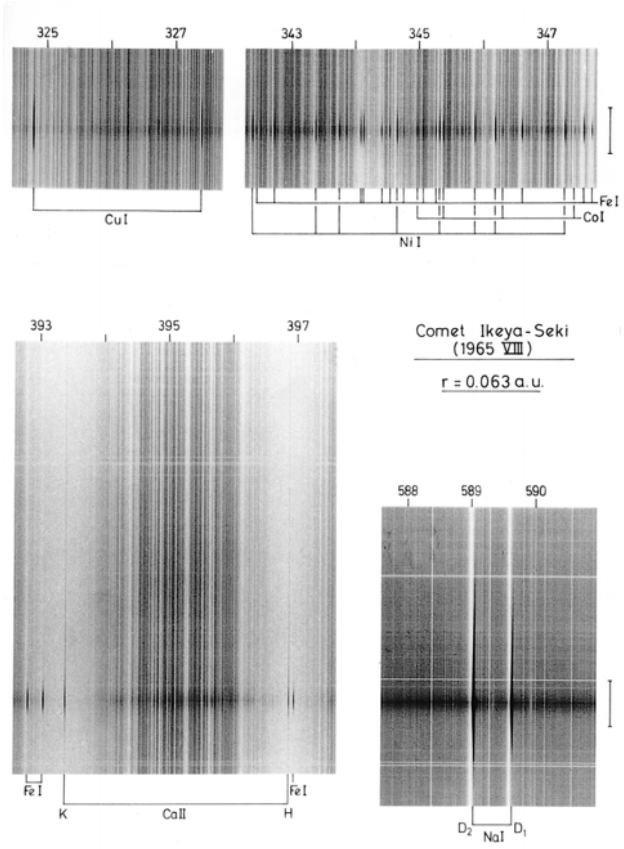

Figure 4. Sample portions of spectra obtained when Comet Ikeya-Seki was about 14 solar radii from the Sun's center after perihelion, in broad daylight. The background is thus the daytime sky spectrum, where numerous Fraunhofer (absorption) lines are seen. On top of this appear (a) a narrow strip of solar radiation scattered by dust particles surrounding the comet's nucleus, the 'continuum', and (b) a number of very short cometary emissions (in black on these negative reproductions) due to neutral copper, iron, cobalt, nickel. The sodium and ionized calcium (H and K) emissions are much longer. The spatial scale is indicated by vertical bars on the right, representing 10 000 km on the comet. The original spectral dispersion was 0.85 mm $Å^{-1}$. A total of approximately 500 emission lines were recorded in the range covered by the series of spectra, 3300–6000 Å; nearly 70% of these emissions belong to Fe I. It is noteworthy that the molecular emissions (not shown here) of CN and, although much weaker, of CH are still present so close to the Sun. (Spectra taken by Livingston and collaborators, Kitt Peak National Observatory, Arizona. Reproduced from Arpigny *et al* 1999 *Atlas of Cometary Spectra* Kluwer, Dordrecht.)

A few sections from these extraordinary spectra of Comet Ikeya-Seki are illustrated in figures 4 and figures 5. Numerous emission lines were observed due mainly to neutral atoms of the iron group, V, Cr, Mn, Fe, Co, Ni and Cu, but also to K, Ca and Ca^+, in addition to Na which first appears near 1 AU from the Sun. This confirmed in particular the presence of a few lines of iron and nickel which had been reported by Copeland and

Lohse after their observations of comet 1882 II with a visual spectroscope. This identification had been questioned in the meantime on the basis of an ill-founded criticism ignoring the peculiar physical conditions prevailing in a comet's atmosphere, a low-density medium very far from the thermodynamic equilibrium generally found in laboratory experiments. The observed atomic emissions are produced, like the molecular emissions seen further away from the Sun, by resonance—fluorescence (absorption of solar radiations by the atoms or molecules, followed by the emission of the various possible transitions issued from the upper energy states excited in this way). Analysing a number of spectra of Ikeya-Seki, Arpigny used the measured line intensities to estimate the relative abundances of the various atoms. A notable result was that some elements, especially Al, Si, Ca and Ti, were found to be appreciably underabundant when referred to Fe and compared with the solar system abundances. Mg was a marginal case. Since these elements are the constituent atoms of high-temperature condensates (e.g. corundum, perovskite, melilite, spinal), a possible interpretation of the deficiencies is that the temperature in the coma of Ikeya-Seki was not high enough when the analysed spectra were taken (around 14 solar radii or 0.065 AU from the Sun) for such resisting materials to be decomposed to any significant degree. No actual measurements of the dust temperature, T_d, were performed at this heliocentric distance, nor any closer to perihelion, but indirect evidence suggests that T_d was probably in the range 1000–1500 K near 0.065 AU. It may be noted that Mg-rich olivines and pyroxenes, recently advocated to be important silicatic components of cometary dust grains, also contain some of the underabundant elements. More detailed quantitative values could not be derived because the available data were unfortunately not sufficient, but it seemed nevertheless safe to conclude that the elemental composition of the dust in the comet was similar to that of the Sun and of chondritic meteorites.

On the other hand, the spatial extension of the Na D emission out to large distances from the center of the comet (see figure 5) despite the very short lifetime of sodium against ionization (of the order of 50 s at $r = 0.04$ AU or 8.6 solar radii) indicates, as pointed out by Spinrad and Miner, and by Huebner, that the Na atoms must be embedded in a compound (or compounds) with a high latent heat of vaporization and thus be produced in a distributed source, not directly from the nucleus. From a study of the sodium velocity field it was also inferred that the precursor dust grains must have been fairly large, more than 20 μm in radius. At the same time, it appears that the cometary sodium seen near 0.5–1 AU necessarily originates from particles of a different nature, containing less refractory Na-rich substances.

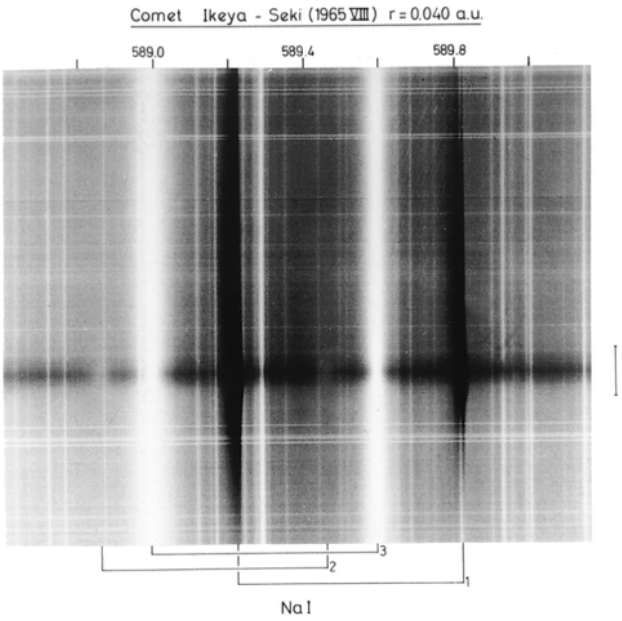

Figure 5. The sodium D lines in comet Ikeya-Seki at $r = 8.5$ solar radii before perihelion (about 2º angular distance), at very high dispersion, 5 mm $Å^{-1}$. This spectrum provides a nice illustration of the Doppler effect. Three doublets can be distinguished: (1) the cometary emissions, here displaced longward by the comet's geocentric velocity ($\dot{\Delta} = +118$ km s^{-1}), (2) the D lines in absorption in the dust scattered solar radiation (the 'continuum'), shifted toward shorter wavelengths according to the sum of the heliocentric and geocentric radial velocities ($\dot{r} + \dot{\Delta} = -188 + 118 = -70$ km s^{-1}), and (3) the same in the background sky spectrum (which gives the reference wavelength scale). (Spectra secured by Spinrad and collaborators, Kitt Peak National Observatory, Arizona. Reproduced from Arpigny *et al* 1999 the *Atlas of Cometary Spectra* Kluwer, Dordrecht.)

Besides these spectroscopic observations, the first infrared observations of a comet were conducted on Ikeya-Seki by Becklin and Westphal who detected the thermal emission by the dust grains and followed its evolution as a function of r, from 0.2 to 0.5 AU both before and after perihelion. From the energy distribution at 1.6, 2.0, 3.4 and 10 μm, these authors found that the temperature of the grains was higher than the temperature that would be attained by a gray or black body in equilibrium with the solar radiation at the heliocentric distance of the comet; they also deduced some information on the wavelength dependence of the emissivity of the grain material, which was found to be much lower in the infrared than in the visible. These findings were confirmed in many comets thereafter. It has now been established that the particles responsible for the thermal emission are very small (submicron- to micron-sized) grains made of silicates mixed with absorbing (probably carbonaceous) materials. These tiny particles absorb efficiently the strong visible solar

Dirac House, Temple Back, Bristol, BS1 6BE, UK

radiation, but cannot radiate easily in the infrared; they are therefore overheated. Polarization measurements were made in the tail of the comet, revealing an abrupt variation in the degree of polarization, a reversal from +20% to –40%, which was interpreted as due to a segregation according to grain size along the tail, the grains being presumably composed of slightly absorbing silicates. Attempts were made to observe Comet Ikeya-Seki in the ultraviolet from rockets, as well as in radio wavelengths, but these failed for various reasons, unfortunately.

Conclusion

We started off by stating that Comet Ikeya-Seki was an exceptional object, which is true in some important respects, but at the same time we have reasons to believe that it bears definite similarity to other non-sungrazing comets. Besides the presence of very small, hot dust grains just mentioned and found in many comets, we also note, for instance, that beyond $r = 0.4$ AU, its spectrum showed the usual molecular emission bands due to CN, C_3, CH, C_2 etc. Hence some of its physical and chemical properties may be considered as typical of comets in general. To know these common features in much more detail, especially with regard to the heavy element abundances and the chemical composition of the dust, we await the appearance of another bright member of the Kreutz sungrazing group. We shall then be even better prepared, with present-day highly performing instruments, to study a sungrazer, in particular by multiwavelength, well calibrated measurements, observing the visitor in the ultraviolet, optical, infrared and radio ranges, when close to the Sun and at distance. It will be very important, for the near-perihelion phase, to plan rather tight time sequences and to be ready for the investigation of the spatial distributions of the various emissions: all these observations will have to be carried out in the space of a few hours!

Comet IRAS–Araki–Alcock (C/1983 H1)

A long-period comet discovered independently in 1983 by the IRAS infrared satellite, Genichi Araki and George Alcock. At its closest to Earth, on 11 May, it was just 0.03 AU (4.6 million km) away—the closest approach of any comet since Lexell's Comet of 1770. At this time it was a large diffuse object of magnitude 2, moving rapidly across the sky. There was no discernible tail, just a diffuse coma 2° or 3° across, and more extended on the sunward side of the nucleus. Radar observations showed the nucleus to have a diameter of 9.3 km. Perihelion (0.99 AU) was on 21 May. The period is approximately 1000 years; the eccentricity is 0.99, and the inclination 73°.

Comet Kohoutek (C/1973 E1)

A long-period comet discovered by Luboš Kohoutek in 1973 March. At that time it was near the orbit of Jupiter, and very bright for a comet at that distance. This led to predictions that it would be exceptionally bright at perihelion (some estimates putting it as high as magnitude −12, rivaling the full Moon), which attracted great media interest. However, the comet failed to brighten significantly as it approached the Sun. Following its perihelion passage (0.14 AU) on 28 December, it appeared in the evening sky in January 1974 at magnitude 4 with a tail 25° long. In this respect Comet Kohoutek failed to live up to its promise. But because of the great expectations it was targeted more than any previous comet had been, and was the subject of an international effort that would be surpassed only by the 1986 International Halley Watch. Comet science was significantly advanced as a result. It is possible that Kohoutek was making its first visit from the Oort Cloud to the inner solar system. This would account for its brightness at the distance of Jupiter, as it would then have been a pristine object outgassing the most volatile of its constituents. The inclination is 14°, and the eccentricity is quoted as 1, meaning that its period and aphelion distance are almost indeterminately large.

Comet LINEAR (C/1999 S4)

Comet C/1999 S4A (LINEAR) was found by the automatic minor planet search programme LINEAR based in New Mexico. In July 2000, the comet disintegrated completely as it made its closest approach to the Sun, at 71 million miles. At least 16 fragments, resembling 'mini-comets' with tails, were then imaged by the HUBBLE SPACE TELESCOPE.

Results from observations of the debris include evidence that comet impacts may have played a significant role in the formation of LIFE ON EARTH by providing most of the water in the Earth's oceans, as well as organic material. LINEAR is the first comet observed to have a composition that would allow it to carry the same type of water as found in oceans on Earth.

Comet Swift–Tuttle (109P/Swift–Tuttle)

A short-period comet discovered in 1862 independently by several observers, the first of which were Lewis Swift and Horace Tuttle. At its brightest it reached magnitude 2 and showed a tail over 25° long. Subsequent calculations indicated that the period was around 120 years, but searches in the early 1980s failed to find it. The comet was not recovered until September 1992, as a 'new' comet reported by Tsuruhiko Kiuchi. At this apparition it reached fifth magnitude and developed a 7° tail; perihelion (0.96 AU) was on 12 December. The nucleus showed one particularly active jet, observations of which indicated a rotation period of 2.9 days. This activity is thought to be responsible for non-gravitational forces which cause the period to vary from a value predicted from gravitational perturbations. The comet was subsequently identified with Kegler's Comet of 1737, and with two comets recorded in Chinese annals from 68 BC and AD 188. On its present orbit the comet has an estimated period of 135 years; its eccentricity is 0.96 and its inclination 113°. Debris from the comet forms the Perseid meteor stream.

Comet Tempel–Tuttle (55P/Tempel–Tuttle)

A short-period comet discovered independently by Ernst Tempel in December 1865 and by Horace Tuttle in January 1866. It was determined to have a period of around 33 years. Studies by Giovanni Schiaparelli showed a very close match between the orbital elements of the comet and those of the Leonid meteor stream, which had produced a spectacular meteor storm in November 1866; this was the first successful demonstration of a link between comets and meteors. The comet was not seen on its next two expected returns in 1899 and 1932 (and there were no Leonid meteor storms in those years). It was recovered in 1965, but only as a distant sixteenth-magnitude object (and another spectacular Leonid storm followed in 1966). At the 1998 apparition it reached fifth magnitude; as on previous occasions, it showed no tail. In 1366 it is calculated to have reached magnitude 3 and to have passed just 0.023 AU (3.4 million km) from the Earth—the third-closest approach of any recorded comet. The perihelion distance is 0.98 AU; the eccentricity is 0.90, and the inclination 163°.

Cosmic Rays: Propagation in the Heliosphere

Cosmic rays consist predominantly of atomic nuclei stripped of their electrons, with a small admixture, of order 1%, of electrons and positrons. Their energies range from a few MeV to more than 10^{20} eV, but only cosmic rays with energies below a few 10s of GeV are significantly affected by heliospheric processes. Because all cosmic rays carry an electrical charge, propagation of cosmic rays in the heliosphere is controlled by their interaction with the interplanetary magnetic field. If there were no magnetic field, cosmic rays would pass through the solar system without hindrance.

The processes that affect propagation of cosmic rays through the field are (1) gyration about the lines of force of the magnetic field, (2) scattering from irregularities in the field, (3) drift motions imposed by the large scale gradients and curvature of the field, and (4) adiabatic deceleration, which arises as a result of their coupling through the field to the expansion of the radially outflowing SOLAR WIND. The gyrational motion allows the particles to propagate easily along a field line, which corresponds to the so-called guiding center of the particle's motion, but prevents significant flow perpendicular to the field. The scattering slows the motion along the fields but can also produce transport perpendicular to the field by changing the guiding center of the particle from one field line to an adjacent one. The drifts are determined by the global geometry of the interplanetary field and provide for organized, as opposed to diffusive, cross-field flows. The adiabatic deceleration changes the energy of particles in the solar wind and is the principal source for the flux of particles observed at energies below a few hundred MeV/nucleon in the inner heliosphere. Since particles with these low energies in the interstellar medium are excluded from the inner heliosphere by the solar wind and interplanetary magnetic field, the low-energy cosmic rays observed near Earth entered the heliosphere at higher energies and were decelerated to their observed energies. A cosmic ray may lose several hundred MeV to adiabatic deceleration during propagation from the boundary of the heliosphere in to the orbit of Earth, with a wide distribution of energy losses depending on the actual path taken by the individual particles.

A comprehensive description of the present state of theory and observation of the propagation of cosmic rays in the heliosphere can be found in the book '*Cosmic Rays in the Heliosphere*' (Fisk *et al* 1998). This brief article can only summarize the most important points.

The interplanetary magnetic field, which controls the propagation, has its origin at the Sun and is carried outward by the electrically conducting plasma of the solar wind (see SOLAR WIND: MAGNETIC FIELD). Since the source of the heliospheric magnetic field is the solar field, the overall magnetic structure of the heliosphere is determined by the magnetic structure of the Sun. This structure is not static but undergoes dramatic changes in the course of an 11 yr solar activity cycle. These changes strongly affect propagation of the cosmic rays.

At solar minimum, the overall solar field is predominantly that of a dipole with a small tilt, of order 10° or so, from the rotation axis of the Sun. As discussed in the article on the solar wind magnetic field, field lines from the open polar coronal holes expand near the Sun and are drawn out by the solar wind to fill each hemisphere of the heliosphere. Thus the interplanetary magnetic fields in the north and south hemispheres of the heliosphere have opposite magnetic polarity. The opposing polarities are separated by a thin near-equatorial current sheet. As a result of rotation of the Sun under the radially expanding solar wind, the individual field lines trace out Archimedean spirals in interplanetary space. The solar wind has typical velocities of $\sim$400 km s^{-1} near the equator and 800 km s^{-1} at high latitudes. The rate of solar rotation Ω about 13.8° day^{-1} near the equator, and the solar wind velocity V_{sw} determine the angle ϕ of the spiral to the radial direction through the relation

$$\phi = \tan^{-1}(r \cos\theta \Omega / V_{sw}) \qquad (1)$$

where r is the radius and θ the latitude. Near the ecliptic this angle is about 45° at the orbit of Earth, and it increases to $\sim$80° near the orbit of Jupiter. Since the heliosphere most likely has a radius of order 100 AU, the field is essentially tangential through most of the heliosphere. If cosmic rays were to follow the field their path lengths from the solar wind termination shock at about 100 AU to Earth at 1 AU could be as great as $\sim$5000 AU. In actuality, the cosmic rays experience scattering from field irregularities during their propagation, and the effects of scattering and the continuing outward convection of the field by the solar wind result in a significant reduction in the cosmic ray intensity in the inner heliosphere compared with that in nearby interstellar space. This reduction in intensity is called solar modulation, and it is effective at all times, even at solar minimum.

In the course of a SOLAR CYCLE, the effective tilt of the solar dipole field increases as solar activity increases, and large local fields associated with active regions begin to make significant contributions to the overall field, in effect increasing the importance of higher-order multipoles in the field. At solar maximum, the dipole component is no longer the dominant component, and the field at the Sun and, by extension, in interplanetary space, becomes very complicated. In addition, the increased solar activity results in increased generation of transient disturbances, such as SOLAR CORONAL MASS EJECTIONS, in the solar wind, which further distort the magnetic field. In response to this increase in field complexity, the cosmic ray intensity throughout the heliosphere is reduced markedly from its solar minimum levels.

As activity diminishes following solar maximum, the field begins to simplify and, as solar minimum approaches a new dipole component, with a sign opposite that of the previous solar minimum, becomes dominant. Thus the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

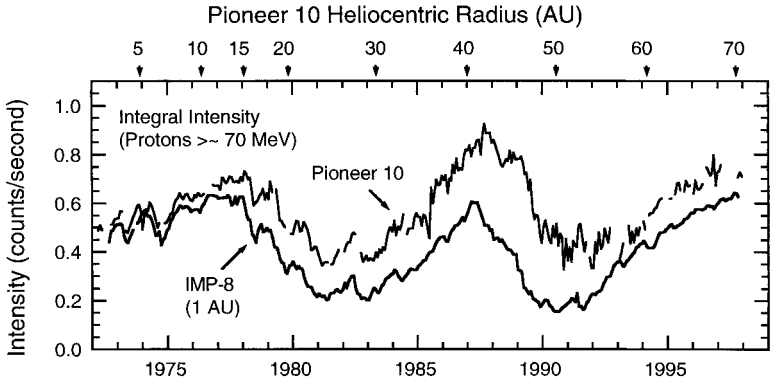

Figure 1. 27 day average intensities of cosmic rays, primarily protons with energy >70 MeV, as measured by University of Chicago instruments on IMP-7 and 8 in Earth orbit and on Pioneer 10 to radii beyond 60 AU from the Sun. IMP intensities have been normalized to match the Pioneer intensities observed at launch in 1972 to correct for the different acceptance factors of the instruments. Effects of the 11 yr solar activity cycle on the cosmic ray intensity are evident, as is the outward propagation of changes in modulation.

solar field, and the heliospheric field with it, reverse sign every 11 yr. For cosmic rays the result of this evolution is the observed 11 yr variation in the cosmic ray intensity, known as the solar cycle modulation (see COSMIC RAYS). As an example, figure 1 shows the effects of this modulation as measured at Earth and at PIONEER 10 to distances beyond 60 AU from the Sun during two cycles of solar activity. The outward propagation of the changes in modulation, representing convection of the changed magnetic structure by the solar wind, is clearly visible, especially for the brief solar minimum of 1987 when the modulation at Earth began to increase even as it was still decreasing at Pioneer 10. Since the average solar wind velocity near the ecliptic is about 400 km s^{-1}, or 0.23 AU day^{-1}, changes observed at 1 AU may not be observed until many months later in the outer heliosphere.

Also apparent in figure 1 is the gradually increasing flux measured at Pioneer 10 compared with that at IMP-8. This increase results from the radial gradient of the cosmic ray intensity, reflecting the fact that the cosmic rays in the outer heliosphere undergo less modulation than those in the inner heliosphere. The magnitude of the gradient is a few per cent per AU, depending on particle energy and species, and is largest in the inner heliosphere. The largest gradients observed, as large as 15–20% AU^{-1} in the inner heliosphere, are for the low-energy anomalous components (see ANOMALOUS COSMIC RAYS) which are accelerated at the solar wind termination shock. Study of the solar cycle modulation provides some of our best information concerning the propagation of cosmic rays in the heliosphere.

Other information that is of critical importance for determining the nature of transport of charged particles in the heliosphere comes from the study of solar energetic particle events, the so-called solar cosmic rays. This aspect has been thoroughly reviewed by Kunow *et al* (1990). During the onset of a solar particle event, the first-arriving particles typically arrive in a very anisotropic flow along the magnetic field direction. The time profile of the arriving particles provides information concerning the scattering properties of the interplanetary magnetic field. Figure 2 shows a time–intensity profile for one of the largest solar energetic particle events ever recorded, which was observed by ground-based detectors of atmospheric radiation induced by cosmic rays in February 1956. This event has features typical of many solar particle events. The rapid onset implies that the particles injected in a burst at the Sun arrive with little scattering between the Sun and the Earth, suggesting a mean free path between scatterings of the order of 1 AU. The slower exponential decay implies the existence of significant scattering beyond the orbit of Earth, which acts to confine the particles in the heliosphere and delay their escape into the interstellar medium. The observations reproduced here in fact provided the first evidence for the existence of the heliosphere. At high energies, such as shown in figure 2, the time scale of a typical event is hours. At lower energies of a few MeV, which can be observed only from space, the time scale for an event from onset until return to normal quiet time intensities may be many days, even weeks for large events.

Scattering of cosmic rays by the interplanetary magnetic field is a result of the interaction between the charged particles spiraling along the field lines and irregularities in the field. If the irregularities are represented by a spectrum of waves through a Fourier transform, the strongest scattering is produced by waves whose wavelength is resonant with the spiraling motion of the particles as they move along the field. Thus the scattering effect depends on the energy and the pitch angle (angle of the velocity vector with respect to the magnetic field) of the particles and on the mean field strength. The effect of the scattering is to modify the pitch angle and/or to displace the guiding center of the particle's gyromotion normal to the field, by, on average, about one gyroradius.

An extensive literature exists concerning attempts to derive the particle scattering properties of the field from observations of the spectrum of irregularities in the field. (For entry points, see Giacalone 1998, Burger and Hattingh

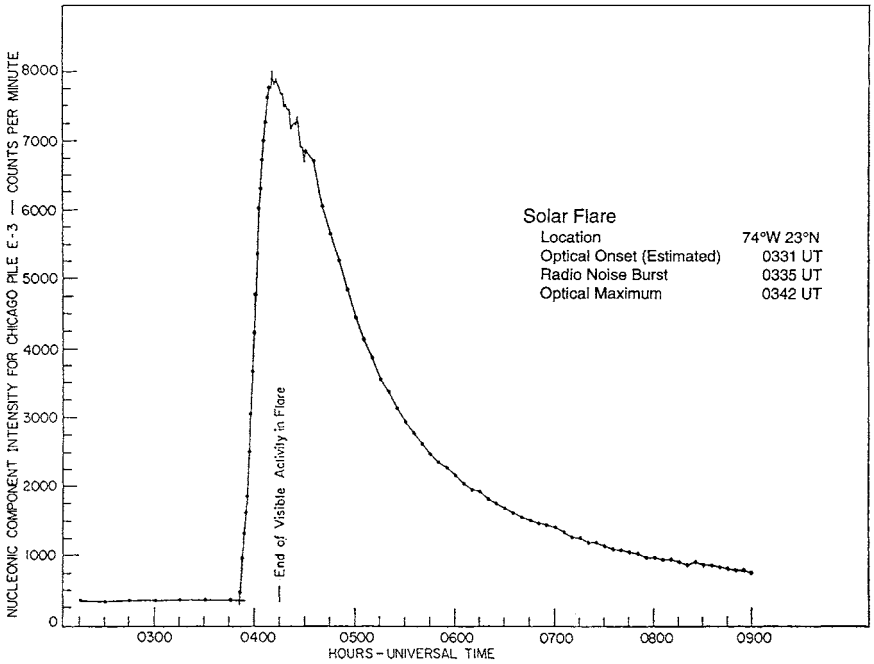

Figure 2. Intensity of ground-level neutrons produced by protons with energies above about 1 GeV interacting in the atmosphere following the 23 February 1956 solar flare, one of the largest ever recorded. The prompt rise implies a long scattering mean free path between the Sun and the Earth, while the extended decay provided the first evidence for an extended scattering region beyond the Earth that we now know as the heliosphere. (Adapted from Meyer *et al* 1956.)

1998). Unfortunately, the effort has still not been fully successful.

In modeling the effects of scattering on modulation of cosmic rays, and of the propagation of solar energetic particles, it is usual to describe the scattering by introducing a diffusion coefficient, κ which may be broken into components $\kappa_\parallel$ parallel to the field and $\kappa_\perp$ perpendicular to the field. In particular, computational models for the modulation of cosmic rays typically use the radial diffusion coefficient

$$\kappa_{rr} = \kappa_\parallel \cos^2\phi + \kappa_\perp \sin^2\phi \qquad (2)$$

as a parameter, where ϕ is the spiral angle of the interplanetary field with respect to the radius vector from the Sun. Throughout most of the heliosphere, $\cos^2\phi$ is approximately zero so that the values of the diffusion coefficient reflect primarily diffusion across the mean field. Typical forms for the diffusion coefficient are $\kappa = A\beta P^\alpha (B_0/B)$ where β is the particle velocity as a fraction of the speed of light, P is the particle magnetic rigidity, or momentum per unit charge, A is a constant and B is the magnetic field strength referred to a reference field B_0. The value of the exponent α is in the range 0–1, and the values of κ_r found to fit observations are typically a few times 10^{22} cm^2 s^{-1} at the orbit of Earth for protons with energies of about 1 GeV. The values increase with radius as a result of the decline in B, which, when the field becomes nearly tangential, decreases as $1/r$.

The deduced values of κ_{rr} pose a particular challenge for theories of the propagation since it has been difficult to achieve rapid enough transport across the mean field direction to match observations. For cross-field propagation due only to scattering, a rough upper limit on the perpendicular diffusion coefficient comes from assuming translation by one gyroradius in the period of one gyration about the field. For ~1 GeV particles near the orbit of Earth, this limit is about 10^{20} cm^2 s^{-1}, or less than 1% of the size of the diffusion coefficient deduced from observations.

Direct observations also clearly require much more efficient transport. As an example of observations which require rapid latitudinal transport, figure 3 shows the persistence to heliospheric latitudes of ~70°–80° of variations in the cosmic ray intensity with the 26 day period of the solar rotation that were induced by solar wind stream interactions near the equator. As shown in the figure, fast solar wind overtaking slow wind produces a region of compressed field, which yields a reduced diffusion coefficient that locally increases the strength of the modulation of cosmic rays. In addition, shocks which accelerate particles to energies of a few MeV may form on the leading and trailing edges of the interaction region. Since the streams are rooted at the Sun, the whole structure rotates with the Sun, giving rise to the name corotating interaction regions (CIRs) (see SOLAR WIND: COROTATING INTERACTION REGIONS). Near solar minimum, the CIRs are confined primarily to the heliospheric equatorial

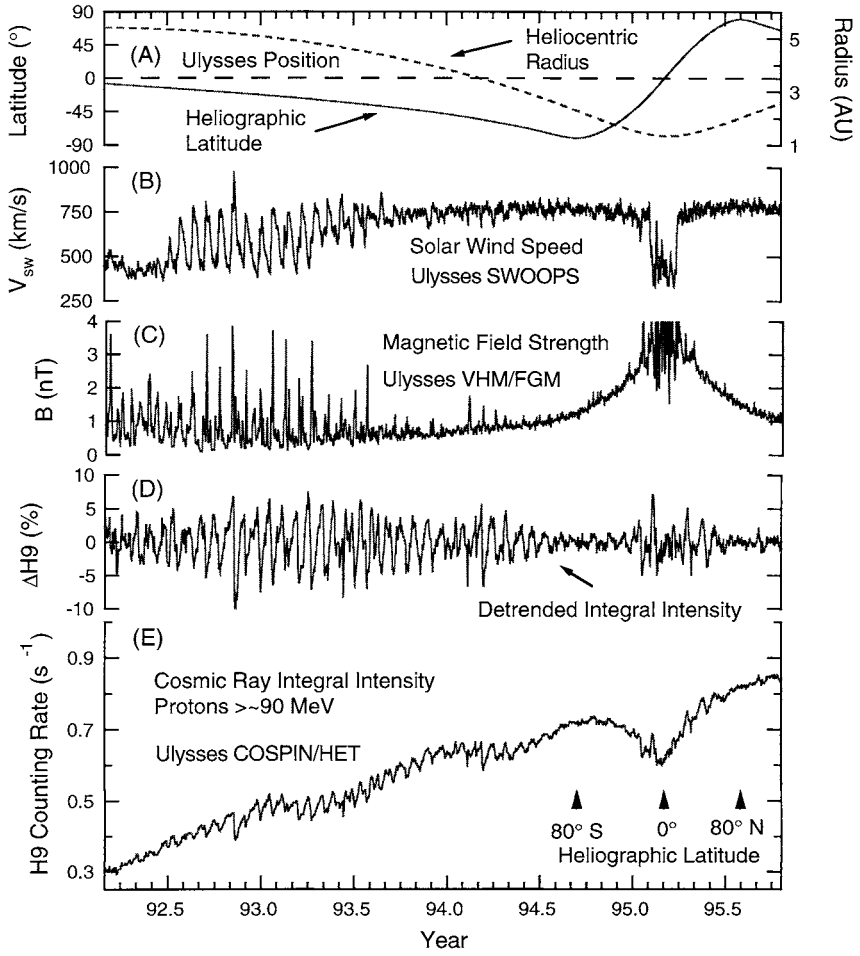

Figure 3. (A) Ulysses position in heliocentric radius and heliographic latitude (B) 6 h average solar wind speeds and (C) daily average magnetic field strengths measured by the Ulysses SWOOPS (Bame *et al* 1992) and VHM/FGM (Balogh *et al* 1992) experiments, respectively; (D) daily average detrended integral intensity of cosmic rays derived by subtracting 27 day running average intensities from (E) the daily intensities measured by the COSPIN/HET experiment (Simpson *et al* 1992). The modest increase of the cosmic ray intensity towards high latitudes is clearly shown by the dip near the equator as Ulysses traveled rapidly from the south to the north polar regions in 1994–1995. The overall increase in intensity from 1992 through to 1995 is the result of decreasing modulation in the approach to solar minimum. (Adapted from Zhang 1997.)

zone where the high-latitude fast wind and the equatorial slow wind can interact. Observation of the cosmic ray intensity variations caused by CIRs at high latitude requires that the cross-field transport take place in a time short compared with the 26 day rotation period of the Sun. Otherwise, the variations would be wiped out. This requires cross-field diffusion coefficients of order 10–20% of the size of diffusion coefficients parallel to the field, or more than a factor of 10 greater than can be explained by scattering theory. At lower energies of a few MeV, recurrent increases attributed to particles accelerated at the CIR shocks have also been seen at high latitudes, raising even greater difficulties for transport theory. For a full discussion of the observations see Simnett *et al* (1998).

Transport across the mean field can be greatly enhanced by systematic motions of the field lines with respect to the mean field direction. Two mechanisms have been identified that may contribute significantly to propagation of energetic particles across the field. The first, first recognized by Jokipii and Parker (1969), is that the solar magnetic field is dragged around on the surface of the Sun by the large-scale convective motions that form the supergranulation network. Since the interplanetary field is rooted in the solar field, the transverse motions imposed by this convective turbulence are carried out into the interplanetary medium. As a result, the interplanetary field lines themselves undergo a random walk in both longitude and latitude. This braiding of the interplanetary field lines then provides an efficient means of enhancing the effect of scattering in transporting particles across the mean field, since a single scattering may transfer a particle's guiding center to a field line that diverges rapidly

from the original field line.

A more ordered motion of the field lines has been suggested by Fisk (1996), who considered the implications for the field lines of the observations that (a) the magnetic axis of the Sun is inclined to the rotation axis and, in the corona, seems to rotate rigidly with the equatorial rotation rate of the Sun and (b) the photosphere, in which individual field lines are rooted, exhibits differential rotation, rotating significantly more slowly at polar latitudes than at the equator. The result is significant latitudinal mixing of field lines, providing direct magnetic connections between equatorial and polar regions of the heliosphere over a radial range of order 15 AU. Longitudinal mixing would also be expected, but the model was proposed, and has been most closely examined, as a means of explaining the rapid latitudinal transport of particles that seems to be required by Ulysses observations (see SOLAR WIND: ULYSSES).

Despite many years of work, however, a convincing understanding of cross-field diffusive transport remains to be achieved. In particular, it is very difficult to derive experimental tests to isolate the effects of the field line random walk or the mixing driven by the differential rotation. All that is certain is that particles, while guided by the field lines, show surprising ability to diffuse in the direction perpendicular to the mean field as well.

A more systematic motion across the field is produced by the gradient and curvature drifts in the heliospheric magnetic field. The spiral nature of the average interplanetary field provides curvature on a global scale, and the progressive weakening of the field as the solar wind carries it outwards through the heliosphere provides a global gradient in the field. By the basic physics of charged particle motion in a non-uniform field, therefore, a globally organized drift of cosmic rays through the heliosphere is generated. The sense of the drift is such that when the north pole of the Sun is a positive magnetic pole, positively charged cosmic rays (nucleons) drift from the polar regions of the heliosphere toward the equator and then rapidly outward along the equatorial current sheet. Electrons, on the other hand, drift inwards along the current sheet and towards the poles above and below the current sheet. 11 yr later, when the magnetic poles of the Sun have the reverse polarity, the drift patterns are also reversed. The drift velocities can be substantial. For particles with magnetic rigidity P, charge q and velocity β, the drift velocity is given by

$$\boldsymbol{V}_{\mathrm{d}} = (\beta P c/3q)\boldsymbol{\nabla} \times (\boldsymbol{B}/B^2) \tag{3}$$

where $\boldsymbol{B}$ is the vector interplanetary field. For 0.1 GeV protons near the orbit of Earth in an ideal Parker spiral field, this velocity is approximately 300 km s^{-1}, comparable with the solar wind velocity. At higher energies, the ideal drift velocity can substantially exceed the solar wind velocity through much of the heliosphere. However, these velocities are directed and not diffusive. Thus, since for the period shown in figure 3 the drift velocities of protons were directed from the poles towards the equator, it would be difficult to invoke drifts to explain the observation of intensity variations at high latitudes impressed by CIRs at low latitudes.

The effect of drifts is substantially diminished in the real field of the heliosphere by the irregularities in the field imposed both at the Sun and by the evolution of structures in the solar wind. CIRs, coronal mass ejections, shear flows in the solar wind, waves and turbulence in the solar wind flow, and many other non-uniformities distort the fields and interrupt the drift flow. At low latitudes, the variable tilt of the heliomagnetic equator translates into waviness of the heliospheric equatorial current sheet as the Sun rotates and the field is carried outwards. This waviness, which varies during the solar cycle, increases the length of the drift path along the sheet and also the probability of loss of particles from the current sheet region. At high latitudes, where from equation (1) one might expect nearly radial fields as $\cos\theta$ approaches 0, the effect of small transverse fluctuations imposed by convective motions at the Sun destroys the field coherence necessary for the full effect of drifts. As first noted by Jokipii and Kota (1989), the fluctuations produce transverse components in the field that vary with radius as $1/r$, whereas the radial components vary as $1/r^2$. Thus beyond a few AU from the Sun transverse components dominate, and the field is essentially tangential. As a result, it is as difficult for cosmic rays to penetrate the polar regions of the heliosphere as it is in the equatorial regions. This has been confirmed by observations from the Ulysses mission, which show both the transverse fluctuations in the field and a change of less than a factor of 2 in cosmic ray intensity from the equator to the pole near solar minimum.

Nevertheless, the effect of drifts, although reduced, has been demonstrated by the observation of variations in the modulation dependent on the sign of the particle charge, to which all major modulation processes except drifts are insensitive, and by confirmation of many predictions of drift models that are difficult to understand in the absence of drifts, such as the alternating broad and narrow shapes of the cosmic ray intensity profiles at successive solar minima (cf Figure 1), reflecting the alteration of the drift paths through the heliosphere imposed by the reversal of the solar dipole field.

The present state of the understanding of the propagation of charged particles in the heliosphere is mixed. The important processes have been characterized in gross terms and models have been developed that, using a number of adjustable or observationally defined parameters, produce reasonable and consistent descriptions of the observed phenomena. However, detailed physical understanding of the characteristics of the propagation remains as work in progress.

Cosmological Model

An idealized picture of the overall structure of the universe and its evolution that may be tested by comparing its predictions with observational data. For simplicity, most cosmological models ignore individual galaxies and clusters, and treat the matter and radiation content of the universe as if it were smeared out into an idealized smooth distribution that is sometimes called 'the substratum'. Practically all cosmological models incorporate the cosmological principle (that the universe is homogeneous and isotropic) and assume the universality of physical laws (that the laws of nature are everywhere the same). If the universe is homogeneous (the same everywhere), then all fundamental observers (observers who are at rest relative to the substratum in their vicinity) see the same sequence of events in the history of the universe, this sequence of events defining a universal cosmic time.

Most cosmological models are based on the general theory of relativity, in which gravititation is treated as a phenomenon arising from the curvature of space (or, strictly, four-dimensional spacetime) that is induced by the presence of massive bodies. Flat space has zero curvature (in flat space, the shortest distance between two points is a straight line and the sum of the angles in a triangle is 180°). Positive curvature corresponds to a universe of finite volume that is curved in an analogous way to the surface of a sphere (in such a space, 'parallel' lines eventually meet, and the angles in a triangle add up to more than 180°). Negative curvature is analogous to the shape of a saddle (in negatively curved space 'parallel' lines eventually diverge, and the sum of the angles in a triangle is less than 180°).

Different model universes may be generated by selecting different values for fundamental quantities such as mean density and curvature, and by choosing zero or non-zero values for an additional term (the cosmological constant) that appears in Einstein's equations. The standard cosmological models are developed from equations derived by Aleksandr Friedmann (1888–1925) in 1922 and are known, therefore, as Friedmann models. If the cosmological term is assumed to be zero, there are three Friedmann models that equate to the Big Bang universe: the open model (in which space is negatively curved and infinite), the closed model (in which space is positively curved and finite) and the 'flat' model (zero curvature, infinite space). The open universe expands forever, the closed universe expands to a finite size then collapses, and the flat universe is just, but only just, capable of expanding forever. The flat model is also known as the Einstein–de Sitter universe. If a positive value for the cosmological constant is included, models can be constructed in which the expansion rate of the universe accelerates.

Cosmological Principle

A fundamental postulate of cosmology that states that, on the large scale, the universe is homogeneous (one large region of space is the same as any other large region of space) and isotropic (looks the same in every direction). This principle implies that our Galaxy is not located at any special or privileged position in the universe and that any observer on any galaxy will see the same general features of the universe as we do. The cosmological principle is sometimes called the Copernican principle after the Polish cleric who, in 1543, dethroned the Earth from its previously assumed central position in the cosmos.

An extension of the cosmological principle, known as the perfect cosmological principle, postulates that, on the large scale, the universe looks the same everywhere, in all directions, *at all times*. If valid, the perfect cosmological principle would require that the large-scale appearance of the universe does not change with time and would preclude the Big Bang model of the universe. It was proposed in 1948 by Hermann Bondi and Thomas Gold as the basis of their formulation of the steady-state theory. Although the cosmological principle is widely assumed to be valid (although the degree to which it is true depends on the scale over which homogeneity and isotropy is averaged), the perfect cosmological principle is untenable in the light of modern observational evidence.

Cosmology

The study of the structure, origin and evolution of the universe as a whole.

Observationally, luminous matter in the universe is distributed in a clumpy fashion, being aggregated together into individual galaxies, groups of galaxies, clusters and superclusters. On the very large scale, however, the universe appears to be homogeneous (i.e. is the same everywhere) and isotropic (i.e. looks the same in every direction). This implies that all observers will see the same large-scale view of the universe regardless of where they are located. No individual galaxy or observer occupies a privileged position, and the universe has no definable center or edge.

During the 1920s, Edwin P Hubble (1889–1953) showed that all galaxies beyond our immediate local group have redshifts in their spectra and that the magnitude of the redshift is proportional to the distance of the galaxy. If the redshift is interpreted as a Doppler effect, Hubble's observations implied that all galaxies are receding with speeds proportional to their distances, a relationship which is now known as the Hubble law. Subsequent observations have confirmed that the Hubble law holds good to very large distances. These observations imply that each galaxy (or, strictly, each cluster of galaxies), is receding from every other one and that the whole universe is expanding.

The observed recession of the galaxies is consistent with the Big Bang theory, which implies that the universe originated a finite time ago (probably between 10 and 15 billion years ago) by expanding from a hot dense initial state. The hot Big Bang theory provides a good explanation of many facets of the observed universe, including the recession of the galaxies, the relative abundance of the lightest chemical elements, and the existence and properties of the cosmic microwave background radiation (a dilute background of microwave radiation that permeates the universe). A more recent adjunct to the theory, the inflationary hypothesis, contends that at a very early stage in its history, the universe experienced a brief, but very dramatic, period of accelerating expansion. This hypothesis, if valid, provides an explanation for several features of the universe, including its homogeneity and isotropy, which cannot directly be explained by the standard Big Bang model. However, how, when, and in what order galaxies, clusters and superclusters were formed remains an unresolved question.

Another major issue in modern cosmology is the question of whether or not the universe will continue to expand forever. In the absence of any other force, gravity is expected to be slowing the rate of expansion. If the mean density of the universe exceeds a particular value, called the critical density, the expansion will cease at some time in the future and the universe will then begin to contract, slowly at first and then ever more rapidly until all of its matter and radiation collides in a 'big crunch'. A universe of this kind is called 'closed'. If the mean density is less than critical, the universe will expand forever, and is called 'open'. The dividing line between these two alternatives is a universe where the mean density is exactly equal to the critical density and in which the speeds of recession of the galaxies slow down ever closer to zero but do not become zero until the infinite future. This case is called the 'flat' universe (or the Einstein–de Sitter universe) because, in such a universe, space, on the large scale, has zero net curvature.

Whether the universe is open, flat or closed may, in principle, be determined by measuring the rate at which the expansion is decelerating or by determining the mean density of matter and radiation in the universe. Although many theoretical cosmologists favor 'flat' or 'closed' models, and the observational data are far from conclusive, the balance of recent evidence appears to favor the open model.

Cosmology Standard Model

COSMOLOGY in the modern sense of quantitative study of the large-scale properties of the universe is a surprisingly recent phenomenon. The first galaxy RADIAL VELOCITY (a blueshift, as it turned out) was only measured in 1912, by Slipher. It was not until 1924 that Hubble was able to prove that the 'nebulae' were indeed large systems of stars at vast distances, by which time it was clear that almost all galaxies had spectral lines displaced to longer wavelengths. Subsequent observations increasingly verified Hubble's (1929) linear relation between distance d and the recessional velocity inferred if redshift was interpreted as a Doppler shift:

$$v = Hd.$$

The theoretical groundwork for describing the universe via GENERAL RELATIVITY was already in place by the mid-1920s, so that it was not long before the basic observational fact of an expanding universe could be given a relatively standard interpretation. The main observational and theoretical uncertainties in this interpretation concern the matter and energy content of the universe. Different possibilities for this content generate very different COSMOLOGICAL MODELS. The purpose of this article is to outline the key concepts and practical formulae of importance in understanding these models, and to show how to apply them to astronomical observations.

Isotropic spacetime

Modern observational cosmology has demonstrated that the real universe is highly symmetric in its large-scale properties, but it would in any case make sense to start by considering the simplest possible mass distribution: one whose properties are homogeneous (uniform density) and isotropic (the same in all directions). The next step is to solve the gravitational field equations to find the corresponding metric. Many of the features of the metric can be deduced from symmetry alone—and indeed will apply even if Einstein's equations are replaced by something more complicated. These general arguments were put forward independently by H P Robertson and A G Walker in 1936.

Consider a set of 'fundamental observers', in different locations, all of whom are at rest with respect to the matter in their vicinity. We can envisage them as each sitting on a different galaxy, and so receding from each other with the general expansion (although real galaxies have in addition random velocities of order 100 km s^{-1} and so are not strictly fundamental observers). A global time coordinate t is supplied by the time measured with the clocks of these observers—i.e. t is the proper time measured by an observer at rest with respect to the local matter distribution. The coordinate is useful globally rather than locally because the clocks can be synchronized by the exchange of light signals between observers, who agree to set their clocks to a standard time when for example the universal homogeneous density reaches some given value. Using this time coordinate plus isotropy, we already have enough information to conclude that the metric must take the following form:

$$c^2\,\mathrm{d}\tau^2 = c^2\,\mathrm{d}t^2 - R^2(t)[f^2(r)\,\mathrm{d}r^2 + g^2(r)\,\mathrm{d}\psi^2].$$

Here, we have used the equivalence principle to say that the proper time interval $\mathrm{d}\tau$ between two distant events would look locally like special relativity to a fundamental observer on the spot: for them, $c^2\,\mathrm{d}\tau^2 = c^2\,\mathrm{d}t^2 - \mathrm{d}x^2 - \mathrm{d}y^2 - \mathrm{d}z^2$. Since we use the same time coordinate as they do, our only difficulty is in the spatial part of the metric: relating their $\mathrm{d}x$ etc to spatial coordinates centered on us.

Distances have been decomposed into the product of a time-dependent scale factor $R(t)$ and a time-independent comoving coordinate r. It is clear that this metric nicely incorporates the idea of a uniformly expanding model with no center. For small separations, where space is Euclidean, we have a simple scaling of vector separations: $\boldsymbol{x}(t) : R(t)\,\boldsymbol{x}(t_0)$. The same law applies irrespective of the origin we choose: $\boldsymbol{x}_1(t) - \boldsymbol{x}_2(t) : R(t)\,[\boldsymbol{x}_1(t_0) - \boldsymbol{x}_2(t_0)]$, and so every observer deduces $\boldsymbol{v} = H\,\boldsymbol{r}$

Because of spherical symmetry, the spatial part of the metric can be decomposed into a radial and a transverse part (in spherical polars, the angle on the sky between two events is $\mathrm{d}\psi^2 = \mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2$). The functions f and g are arbitrary; however, we can choose our radial coordinate such that either $f = 1$ or $g = r^2$, to make things look as much like Euclidean space as possible. Furthermore, the remaining function is determined by symmetry arguments.

Consider first the simple case of the metric on the surface of a sphere. A balloon being inflated is a common popular analogy for the expanding universe, and it will serve as a two-dimensional example of a space of constant curvature. If we call the polar angle in spherical polars r instead of the more usual θ, then the element of length, $\mathrm{d}\sigma$, on the surface of a sphere of radius R is

$$\mathrm{d}\sigma^2 = R^2\left(\mathrm{d}r^2 + \sin^2 r\,\mathrm{d}\phi^2\right).$$

It is possible to convert this to the metric for a 2-space of constant negative curvature by the device of considering an imaginary radius of curvature, $R \to {}_{\mathrm{i}}R$. If we simultaneously let $r \to \mathrm{i}r$, we obtain

$$\mathrm{d}\sigma^2 = R^2\left(\mathrm{d}r^2 + \sinh^2 r\,\mathrm{d}\phi^2\right).$$

These two forms can be combined by defining a new radial coordinate that makes the transverse part of the metric look Euclidean:

$$\mathrm{d}\sigma^2 = R^2\left(\frac{\mathrm{d}r^2}{1 - kr^2} + r^2\,\mathrm{d}\phi^2\right)$$

Dirac House, Temple Back, Bristol, BS21 6BE, UK

where $k = +1$ for positive curvature and $k = -1$ for negative curvature.

This is in fact the general form of the spatial part of the Robertson–Walker metric. To prove this in 3D, consider a 3-sphere embedded in four-dimensional Euclidean space, which is defined via the coordinate relation $x^2 + y^2 + z^2 + w^2 = R^2$. Now define the equivalent of spherical polars and write $w = R\cos\alpha$, $z = R\sin\alpha\cos\beta$, $y = R\sin\alpha\sin\beta\cos\gamma$, $x = R\sin\alpha\sin\beta\sin\gamma$, where α, β and γ are three arbitrary angles. Differentiating with respect to the angles gives a four-dimensional vector (dx,dy,dz,dw), and it is a straightforward exercise to show that the squared length of this vector

$$|(\mathrm{d}x, \mathrm{d}y, \mathrm{d}z, \mathrm{d}w)|^2 = R^2[\mathrm{d}\alpha^2 + \sin^2\alpha(\mathrm{d}\beta^2 + \sin^2\beta\ \mathrm{d}\gamma^2)]$$

which is the Robertson–Walker metric for the case of positive spatial curvature.

This $k = +1$ metric describes a closed universe, in which a traveler who sets off along a trajectory of fixed β and γ will eventually return to their starting point (when $\alpha = 2\pi$). In this respect, the positively curved 3D universe is identical to the case of the surface of a sphere: it is finite, but unbounded. By contrast, the $k = -1$ metric describes an open universe of infinite extent; as before, changing to negative spatial curvature replaces sin α with sinh α, and α can be made as large as we please without returning to the starting point. The $k = 0$ model describes a flat universe, which is also infinite in extent. This can be thought of as a limit of either of the $k = \pm 1$ cases, where the curvature scale R tends to infinity.

The Robertson–Walker metric may be written in a number of different ways. The most compact forms are those where the comoving coordinates are dimensionless. In terms of the function

$$S_k(r) = \begin{cases} \sin r & (k=1) \\ \sinh r & (k=-1) \\ r & (k=0) \end{cases}$$

the metric can be written as

$$c^2\,\mathrm{d}\tau^2 = c^2\,\mathrm{d}t^2 - R^2(t)[\mathrm{d}r^2 + S_k^2(r)\,\mathrm{d}\psi^2].$$

The most common alternative is to use a different definition of comoving distance, $S_k(r) \to r$, so that the metric becomes

$$c^2\,\mathrm{d}\tau^2 = c^2\,\mathrm{d}t^2 - R^2(t)\left(\frac{\mathrm{d}r^2}{1-kr^2} + r^2\,\mathrm{d}\psi^2\right).$$

There should of course be two different symbols for the different comoving radii, but each is often called r in the literature. Finally, a common alternative form of the scale factor is where its present value is set to t)\equiv

$$a(t) \equiv R(t)/R_0.$$

The redshift

How does this discussion relate to HUBBLE'S LAW: $v = Hr$? Comoving coordinates are time independent, so the proper separation of two fundamental observers is just $R(t)\,\mathrm{d}r$, and differentiation gives Hubble's law, $v = H(R\,\mathrm{d}r)$, with

$$H = \frac{\dot{R}}{R}.$$

At small separations, the recessional velocity gives the Doppler shift (see DOPPLER EFFECT):

$$\frac{\nu_{\mathrm{emit}}}{\nu_{\mathrm{obs}}} \equiv 1 + z \simeq 1 + \frac{v}{c}.$$

This defines the REDSHIFT z in terms of the shift of spectral lines. What is the equivalent of this relation at larger distances? Since photons travel on null geodesics of zero proper time, we see directly from the metric that

$$r = \int \frac{c\,\mathrm{d}t}{R(t)}.$$

The comoving distance is constant, whereas the domain of integration in time extends from t_{emit} to t_{obs}; these are the times of emission and reception of a photon. Photons that are emitted at later times will be received at later times, but these changes in t_{emit} and t_{obs} cannot alter the integral, since r is a comoving quantity. This requires the condition $\mathrm{d}t_{\mathrm{emit}} / \mathrm{d}t_{obs} = R(t_{emit}) / R(t_{obs})$, which means that events on distant galaxies time dilate according to how much the universe has expanded since the photons we see now were emitted. Clearly (think of events separated by one period), this dilation also applies to frequency, and we therefore obtain

$$\frac{\nu_{\mathrm{emit}}}{\nu_{\mathrm{obs}}} \equiv 1 + z = \frac{R(t_{\mathrm{obs}})}{R(t_{\mathrm{emit}})}.$$

In terms of the normalized scale factor $a(t)$, $a(t) = (1 + z)^{-1}$. Photon wavelengths therefore stretch with the universe, as is intuitively reasonable.

The meaning of the redshift

For small redshifts, the interpretation of the redshift as a Doppler shift ($z = v/c$) is quite clear. What is not so clear is what to do when the redshift becomes large. A common but incorrect approach is to use the special-relativistic Doppler formula and write

$$1 + z = \left(\frac{1 + v/c}{1 - v/c}\right)^{1/2}.$$

This is wrong in general, but it is all too common to read of the latest high-redshift QUASAR as 'receding at 95% of the speed of light'. The reason the redshift cannot be interpreted in this way is because a non-zero mass density must cause gravitational redshifts.

However, although the redshift cannot be thought of as a global Doppler shift, it is correct to think of the effect as an accumulation of the infinitesimal Doppler shifts caused by photons passing between fundamental observers separated by a small distance:

$$\frac{\delta z}{1+z} = H(z)\,\delta\ell(z)$$

(where $\delta\ldots$ is a radial increment of proper distance). This expression may be verified by substitution of the standard expressions for $H(z)$ and $\mathrm{d}\ldots/\mathrm{d}z$. The nice thing about this way of looking at the result is that it emphasizes that it is momentum that is redshifted; particle de Broglie wavelengths thus scale with the expansion, a result that is independent of whether their rest mass is non-zero.

An inability to see that the expansion is locally just kinematical also lies at the root of perhaps the worst misconception about the BIG BANG THEORY. Many semipopular accounts of cosmology contain statements to the effect that 'space itself is swelling up' in causing the galaxies to separate. In fact, objects separate now only because they have done so in the past; a pair of massless objects set up at rest with respect to each other in a uniform model will show no tendency to separate (in fact, the gravitational force of the mass lying between them will cause an inward relative acceleration). In the common elementary demonstration of the expansion by means of inflating a balloon, galaxies should be represented by glued-on coins, not ink drawings (which will spuriously expand with the universe).

Dynamics of the expansion

The equation of motion for the scale factor can be obtained in a quasi-Newtonian fashion. Consider a sphere about some arbitrary point, and let the radius be $R(trr$, where r is arbitrary. The motion of a point at the edge of the sphere will, in Newtonian gravity, be influenced only by the interior mass. We can therefore apparently write down immediately a differential equation (Friedmann's equation) that expresses conservation of energy: $(\dot{R}r)^2/2 – GM/Rr = constant$. In fact, this equation really requires general relativity: the gravitation from mass shells at large distances is not Newtonian, because space is curved, and so we cannot employ the usual argument about their effect being zero. Nevertheless, the result that the gravitational field inside a uniform shell is zero does hold in general relativity, and is known as Birkhoff's theorem. General relativity becomes even more vital in giving the constant of integration in Friedmann's equation:

$$\dot{R}^2 - \frac{8\pi G}{3}\rho R^2 = -kc^2.$$

Note that this equation covers all contributions to ρ, i.e. those from matter, radiation and vacuum; it is independent of the equation of state.

It is sometimes convenient to work with the time derivative of the Friedmann equation, for the same reason that acceleration arguments in dynamics are sometimes more transparent than energy ones. Differentiating with respect to time requires a knowledge of $\dot{\rho}$, but this can be eliminated by means of conservation of energy: $\mathrm{d}(\rho c^2 R^3) = -p\,\mathrm{d}(R^3)$. We then obtain

$$\ddot{R} = -4\pi G R(\rho c^2 + 3p)/3.$$

Both this equation and the Friedmann equation in fact arise as independent equations from different components of Einstein's equations for the Robertson–Walker metric.

The Friedmann equation is so named because FRIEDMANN was the first to appreciate, in 1922, that Einstein's equations admitted cosmological solutions containing matter only (although it was Lemaître who in 1927 both obtained the solution and appreciated that it led to a linear distance–redshift relation). The term Friedmann model is therefore often used to indicate a matter-only cosmology, even though his equation includes contributions from all equations of state. A common shorthand for relativistic cosmological models, which are described by the Robertson–Walker metric and which obey the Friedmann equation, is to speak of FRW models.

Density parameters etc

According to the Friedmann equation, the 'flat' universe with $k = 0$ arises for a particular critical density. We are therefore led to define a density parameter as the ratio of density to critical density:

$$\Omega \equiv \frac{\rho}{\rho_c} = \frac{8\pi G\rho}{3H^2}.$$

Since ρ and H change with time, this defines an epoch-dependent density parameter. The current value of the parameter should strictly be denoted by Ω_0. Because this is such a common symbol, it is normal to keep the formulae uncluttered by normally dropping the subscript; the density parameter at other epochs will be denoted by $\Omega(z)$. If we now also define a dimensionless (current) Hubble parameter as

$$h \equiv \frac{H_0}{100\ \mathrm{km\ s^{-1}\ Mpc^{-1}}}$$

then the current density of the universe may be expressed as

$$\begin{aligned}\rho_0 &= 1.88 \times 10^{-26}\Omega h^2\ \mathrm{kg\ m^{-3}} \\ &= 2.78 \times 10^{11}\Omega h^2 M_\odot\ \mathrm{Mpc^{-3}}.\end{aligned}$$

A powerful approximate model for the energy content of the universe is to divide it into pressureless matter ($\rho : R^{-3}$), radiation ($\rho : R^{-4}$) and vacuum energy (ρ independent of time—i.e. there is a non-zero cosmological constant). The first two relations just say that the number

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

density of particles is diluted by the expansion, with photons also having their energy reduced by the redshift; the third relation applies for Einstein's cosmological constant. In terms of observables, this means that the density is written as (where the normalized scale factor is $a = R/R_0$).

$$\frac{8\pi G\rho}{3} = H_0^2(\Omega_\mathrm{v} + \Omega_\mathrm{m}a^{-3} + \Omega_\mathrm{r}a^{-4})$$

In terms of the deceleration parameter,

$$q \equiv -\frac{\ddot{R}R}{\dot{R}^2}$$

the $\ddot{R}$ form of the Friedmann equation says that

$$q = \Omega_\mathrm{m}/2 + \Omega_\mathrm{r} - \Omega_\mathrm{v}.$$

Lastly, it is often necessary to know the present value of the scale factor, which may be read directly from the Friedmann equation:

$$R_0 = \frac{c}{H_0}[(\Omega - 1)/k]^{-1/2}.$$

The HUBBLE CONSTANT thus sets the curvature length, which becomes infinitely large as Ω approaches unity from either direction. Only in the limit of zero density does this length become equal to the other common measure of the size of the universe—the Hubble length, c/H_0.

Solutions to the Friedmann equation

The Friedmann equation may be solved most simply in 'parametric' form, by recasting it in terms of the conformal time $\mathrm{d}\eta = c\,\mathrm{d}t/R$ (denoting derivatives with respect to η by primes):

$$R'^2 = \frac{8\pi G}{3c^2}\rho R^4 - kR^2.$$

Because $H_0^2R_0^2 = kc^2/(\Omega–1)$, the Friedmann equation becomes

$$a'^2 = \frac{k}{\Omega - 1}[\Omega_\mathrm{r} + \Omega_\mathrm{m}a - (\Omega - 1)a^2 + \Omega_\mathrm{v}a^4]$$

which is straightforward to integrate provided that $\Omega_\mathrm{v} = 0$. Solving the Friedmann equation for $R(t)$ in this way is important for determining global quantities such as the present age of the universe, and explicit solutions for particular cases are considered below. However, from the point of view of observations, and in particular the distance–redshift relation, it is not necessary to proceed by the direct route of determining $R(t)$.

To the observer, the evolution of the scale factor is most directly characterized by the change with redshift of the Hubble parameter and the density parameter; the evolution of $H(z)$ and $\Omega(z)$ is given immediately by the Friedmann equation in the form $H^2 = 8\pi G\rho/3–kc^2/R^2$. Inserting the model dependence of ρ on a gives

$$H^2(a) = H_0^2[\Omega_\mathrm{v} + \Omega_\mathrm{m}a^{-3} + \Omega_\mathrm{r}a^{-4} - (\Omega - 1)a^{-2}].$$

This is a crucial equation, which can be used to obtain the relation between redshift and comoving distance. The radial equation of motion for a photon is $R\,\mathrm{d}r = c\,\mathrm{d}t = c\,\mathrm{d}R/\dot{R} = c\,\mathrm{d}R/RH$. With $R = R_0/(1+z)$, this gives

$$R_0\,\mathrm{d}r = \frac{c}{H(z)}\,\mathrm{d}z = \frac{c}{H_0}[\Omega_\mathrm{v} + \Omega_\mathrm{m}a^{-3} + \Omega_\mathrm{r}a^{-4} - (\Omega - 1)a^{-2}]^{-1/2}\,\mathrm{d}z.$$

This relation is arguably the single most important equation in cosmology, since it shows how to relate comoving distance to the observables of redshift, Hubble constant and density parameters. The comoving distance determines the apparent brightness of distant objects, and the comoving volume element determines the numbers of objects that are observed. These aspects of observational cosmology are discussed in more detail below.

Lastly, using the expression for $H(z)$ with $\Omega(a)–1 = kc^2/H^2R^2$ gives the redshift dependence of the total density parameter:

$$\Omega(z) - 1 = \frac{\Omega - 1}{1 - \Omega + \Omega_\mathrm{v}a^2 + \Omega_\mathrm{m}a^{-1} + \Omega_\mathrm{r}a^{-2}}.$$

This last equation is very important. It tells us that, at high redshift, all model universes apart from those with only vacuum energy will tend to look like the $\Omega = 1$ model. This is not surprising given the form of the Friedmann equation: provided that $\rho R^2 \to \infty$ as $R \to 0$, the $–kc^2$ curvature term will become negligible at early times. If $\Omega \neq 1$, then in the distant past $\Omega(z)$ must have differed from unity by a tiny amount: the density and rate of expansion needed to have been finely balanced for the universe to expand to the present. This tuning of the initial conditions is called the flatness problem and is one of the motivations for the applications of quantum theory to the early universe.

Matter-dominated universe

From the observed temperature of the microwave background (2.73 K) and the assumption of three species of neutrino at a slightly lower temperature, we deduce that the total relativistic density parameter is $\Omega_\mathrm{r}h^2 \approx 4.2–10^{–5}$, so at present it should be a good approximation to ignore radiation. However, the different redshift dependences of matter and radiation densities mean that this assumption fails at early times: $\rho_\mathrm{m}/\rho_r : (1 + z)^{–1}$. One of the critical epochs in cosmology is therefore the point at which these contributions were equal: the redshift of matter–radiation equality

$$1 + z_\mathrm{eq} \simeq 23\,900\Omega h^2.$$

At redshifts higher than this, the universal dynamics was dominated by the relativistic-particle content. By an

Dirac House, Temple Back, Bristol, BS21 6BE, UK

interesting coincidence, this epoch is close to another important event in cosmological history: recombination. Once the temperature falls below $\approx 10^4$ K, ionized material can form neutral hydrogen. Observational astronomy is only possible from this point on, since Thomson scattering from electrons in ionized material prevents photon propagation. In practice, this limits the maximum redshift of observational interest to about 1100; unless Ω is very low or vacuum energy is important, a matter-dominated model is therefore a good approximation to reality.

By conserving matter, we can introduce a characteristic mass M_*, and from this a characteristic radius R_*:

$$\frac{4\pi G}{3c^2}\rho R^3 = \frac{c}{H_0}\frac{\Omega[k(\Omega-1)]^{3/2}}{2} \equiv \frac{GM_*}{c^2} \equiv R_*$$

where we have used the expression for R_0 in the first step. When only matter is present, the conformal-time version of the Friedmann equation is simple to integrate for $R(\eta)$, and integration of $\mathrm{d}t = \mathrm{d}\eta/R$ gives $t(\eta)$:

$$R = kR_*[1 - C_k(\eta)]$$

$$ct = kR_*[\eta - S_k(\eta)].$$

The evolution of $R(t)$ in this solution is plotted in figure 1. A particular point to note is that the behavior at early times is always the same: potential and kinetic energies greatly exceed total energy and we always have the $k = 0$ form $R{:}t^{2/3}$.

Radiation-dominated universe

At high enough redshifts, the $R{:}t^{2/3}$ law will fail, because radiation pressure will become important. At these redshifts, it is an excellent approximation to ignore the effects of spatial curvature, so that the Friedmann equation for a matter–radiation mix is

$$\dot{a}^2 = H_0^2(\Omega_\mathrm{m}a^{-1} + \Omega_\mathrm{r}a^{-2}).$$

This may be integrated to give the time as a function of scale factor:

$$H_0 t = \frac{2}{3\Omega_\mathrm{m}^2}[(\Omega_\mathrm{r} + \Omega_\mathrm{m}a)^{1/2}(\Omega_\mathrm{m}a - 2\Omega_\mathrm{r}) + 2\Omega_\mathrm{r}^{3/2}]$$

which goes to $\frac{2}{3}a^{3/2}$ for a matter-only model and to $a^2/2$ for radiation only. At early times, the scale factor thus grows as $R{:}t^{1/2}$.

One further way of presenting the model's dependence on time is via the density. Following the above, it is easy to show that

$$t = \begin{cases} \left(\dfrac{1}{6\pi G\rho}\right)^{1/2} & \text{(matter domination)} \\ \left(\dfrac{3}{32\pi G\rho}\right)^{1/2} & \text{(radiation domination).} \end{cases}$$

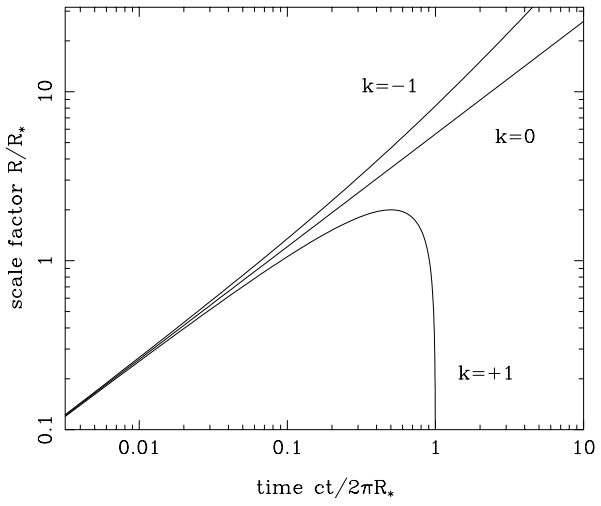

Figure 1. The time dependence of the scale factor for open, closed and critical matter-dominated cosmological models. The logarithmic scale is designed to bring out the early-time behavior, although it obscures the fact that the closed model is a symmetric cycloid on a linear plot of R against t. Reproduced from *Cosmological Physics* (Cambridge University Press).

Models with vacuum energy

The solution of the Friedmann equation becomes more complicated if we allow a significant contribution from vacuum energy—i.e. a non-zero cosmological constant. The Friedmann equation itself is independent of the equation of state, and just says $H^2R^2 = kc^2/(\Omega–1)$, whatever the form of the contributions to Ω. In terms of the cosmological constant itself, we have

$$\Omega_\mathrm{vac} = \frac{8\pi G\rho_\mathrm{vac}}{3H^2} = \frac{\Lambda c^2}{3H^2}.$$

The reason that the cosmological constant was first introduced by Einstein was not simply because there was no general reason to expect empty space to be of zero density, but because it allows a non-expanding cosmology to be constructed. This is perhaps not so obvious from some forms of the Friedmann equation, since now $H = 0$ and $\Omega = \infty$; if we cast the equation in its original form without defining these parameters, then zero expansion implies

$$\rho = \frac{3kc^2}{8\pi GR^2}.$$

Since Λ can have either sign, this appears not to constrain k. However, we also want to have zero acceleration for this model, and so need the time derivative of the Friedmann equation: $\ddot{R} = -4\pi GR(\rho + 3p)/3$. A further condition for a static model is therefore that

$$\rho = -3p.$$

Since $\rho = -p$ for vacuum energy, and this is the only source of pressure if we ignore radiation, this tells us that $\rho = 3\rho_\mathrm{vac}$ and hence that the mass density is twice the vacuum density. The total density is hence positive and $k = 1$; we have a closed model.

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

Notice that what this says is that a positive vacuum energy acts in a repulsive way, balancing the attraction of normal matter. This shows that the static model cannot be stable: if we perturb the scale factor by a small positive amount, the vacuum repulsion is unchanged whereas the 'normal' gravitational attraction is reduced, so that the model will tend to expand further (or contract, if the initial perturbation was negative).

de Sitter space

The endpoint of an outwards perturbation of Einstein's static model was first studied by DE SITTER. This universe is completely dominated by vacuum energy and is clearly the limit of the unstable expansion, since the density of matter redshifts to zero while the vacuum energy remains constant. Consider again the Friedmann equation in its general form $\dot{R}^2 - 8\pi G\rho R^2/3 = -kc^2$: since the density is constant and R will increase without limit, the two terms on the lhs must eventually become almost exactly equal and the curvature term on the rhs will be negligible. Thus, even if $k \neq 0$, the universe will have a density that differs only infinitesimally from the critical, so that we can solve the equation by setting $k = 0$, in which case

$$R \propto \exp(Ht) \qquad H = \left(\frac{8\pi G\rho_{\rm vac}}{3}\right)^{1/2} = \left(\frac{\Lambda c^2}{3}\right)^{1/2}.$$

An interesting interpretation of this behavior was promoted in the early days of cosmology by Eddington: the cosmological constant is what caused the expansion. In models without Λ, the expansion is merely an initial condition: anyone who asks why the universe expands at a given epoch is given the unsatisfactory reply that it does so because it was expanding at some earlier time. It would be more satisfying to have some mechanism that set the expansion into motion, and this is what is provided by vacuum repulsion. This tendency of models with positive Λ to end up undergoing an exponential phase of expansion (and moreover one with $\Omega = 1$) is exactly what is used in inflationary cosmology to generate the initial conditions for the big bang.

The steady-state model

The behavior of de Sitter space is in some ways reminiscent of the steady-state universe, which was popular in the 1960s. This STEADY-STATE THEORY drew its motivation from the philosophical problems of big-bang models—which begin in a singularity at $t = 0$, and for which earlier times have no meaning. Instead, Hoyle, Bondi and Gold suggested the perfect cosmological principle in which the universe is homogeneous not only in space but also in time: apart from local fluctuations, the universe appears the same to all observers at all times. This tells us that the Hubble constant really is constant, and so the model necessarily has exponential expansion, $R : \exp(Ht)$, exactly as for de Sitter space. Indeed, de Sitter space is a steady-state universe: it contains a constant vacuum energy density and has an infinite age, lacking any big-bang singularity. However, de Sitter space is a rather uninteresting model because it contains no matter. Introducing matter into a steady-state universe violates energy conservation, since matter does not have the $p = -\rho c^2$ equation of state that allows the density to remain constant. This is the most radical aspect of steady-state models: they require continuous creation of matter. The energy to accomplish this has to come from somewhere, and Einstein's equations are modified by adding some 'creation' or '*C*-field' term to the energy–momentum tensor:

$$T'^{\mu\nu} = T^{\mu\nu} + C^{\mu\nu} \qquad T'^{\mu\nu}_{;\nu} = 0.$$

The effect of this extra term must be to cancel the matter density and pressure, leaving just the overall effective form of the vacuum tensor, which is required to produce de Sitter space and the exponential expansion. This *ad hoc* field and the lack of any physical motivation for it beyond the cosmological problem it was designed to solve was always the most unsatisfactory feature of the steady-state model, and may account for the strong reactions generated by the theory.

Bouncing and loitering models

Returning to the general case of models with a mixture of energy in the vacuum and normal components, we have to distinguish three cases. For models that start from a big bang (in which case radiation dominates completely at the earliest times), the universe will either recollapse or expand forever. The latter outcome becomes more likely for low densities of matter and radiation, but high vacuum density. It is, however, also possible to have models in which there is no big bang: the universe was collapsing in the distant past, but was slowed by the repulsion of a positive Λ term and underwent a 'bounce' to reach its present state of expansion. Working out the conditions for these different events is a matter of integrating the Friedmann equation. For the addition of Λ, this can only in general be done numerically. However, we can find the conditions for the different behaviors described above analytically, at least if we simplify things by ignoring radiation. The equation in the form of the time-dependent Hubble parameter looks like

$$\frac{H^2}{H_0^2} = \Omega_{\rm v}(1 - a^{-2}) + \Omega_{\rm m}(a^{-3} - a^{-2}) + a^{-2}$$

and we are interested in the conditions under which the lhs vanishes, defining a turning point in the expansion. Setting the rhs to zero yields a cubic equation, and it is possible to give the conditions under which this has a solution, which are as follows.

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

(1) First, negative Λ always implies recollapse, which is intuitively reasonable (either the mass causes recollapse before Λ dominates, or the density is low enough that Λ comes to dominate, which cannot lead to infinite expansion unless Λ is positive).
(2) If Λ is positive and $\Omega_m<1$, the model always expands to infinity.
(3) If $\Omega_m>1$, recollapse is only avoided if Ω_v exceeds a critical value

$$\Omega_v > 4\Omega_m\{\cos[\tfrac{1}{3}\cos^{-1}(\Omega_m^{-1}-1)+\tfrac{4}{3}\pi]\}^3.$$

(4) If Λ is large enough, the stationary point of the expansion is at $a<1$ and we have a bounce cosmology. This critical value is

$$\Omega_v > 4\Omega_m\{f[\tfrac{1}{3}f^{-1}(\Omega_m^{-1}-1)]\}^3$$

where the function f is cosh if $\Omega_m<0.5$, otherwise cos. If the universe lies exactly on the critical line, the bounce is at infinitely early times and we have a solution that is the result of a perturbation of the Einstein static model.

In fact, bounce models can be ruled out quite strongly. The same cubic equations that define the critical conditions for a bounce also give an inequality for the maximum redshift possible (that of the bounce):

$$1+z_B \leqslant 2f[\tfrac{1}{3}f^{-1}(\Omega_m^{-1}-1)].$$

A reasonable lower limit for Ω_m of 0.1 then rules out a bounce once objects are seen at $z>2$.

The main results of this section are summed up in figure 2. Since the radiation density is very small today, the main task of relativistic cosmology is to work out where on the Ω_{matter}–Ω_{vacuum} plane the real universe lies. The existence of high-redshift objects rules out the bounce models, so that the idea of a hot big bang cannot be evaded.

At this point, we have reproduced one of the great conclusions of relativistic cosmology: the universe is of finite age, and had its origin in a mathematical singularity at which the scale factor went to zero, leading to a divergent spacetime curvature. Since zero scale factor also implies infinite density (and temperature), the inferred picture of the early universe is one of unimaginable violence. The term big bang was coined by FRED HOYLE to describe this beginning, although it was intended somewhat critically. The problem with the singularity is that it marks the breakdown of the laws of physics; we cannot extrapolate the solution for $R(t)$ to $t<0$, and so the origin of the expansion becomes an unexplained boundary condition. It was only after about 1980 that a consistent set of ideas became available for ways of avoiding this barrier, in the form of inflationary cosmology.

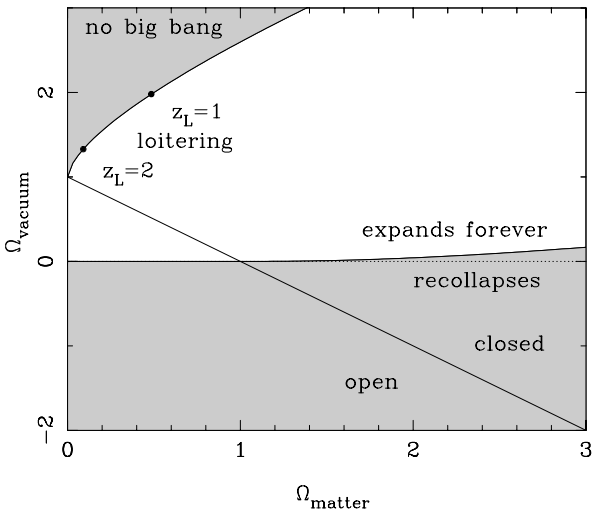

Figure 2. This plot shows the different possibilities for the cosmological expansion as a function of matter density and vacuum energy. Models with total $\Omega>1$ are always spatially closed (open for $\Omega<1$), although closed models can still expand to infinity if $\Omega_v\neq0$. If the cosmological constant is negative, recollapse always occurs; recollapse is also possible with a positive Ω_v if $\Omega_m\gg\Omega_v$. If $\Omega_v>1$ and Ω_m is small, there is the possibility of a 'loitering' solution with some maximum redshift and infinite age (top left); for even larger values of vacuum energy, there is no big-bang singularity. Reproduced from *Cosmological Physics* (Cambridge University Press).

Flat universe

The most important model in cosmological research is that with $k = 0 \Rightarrow \Omega_{total} = 1$; when dominated by matter, this is often termed the Einstein–de Sitter model. Paradoxically, this importance arises because it is an unstable state: as we have seen earlier, the universe will evolve away from $\Omega = 1$, given a slight perturbation. For the universe to have expanded by so many e-foldings (factors of e expansion) and yet still have Ωd1 implies that it was very close to being spatially flat at early times. Many workers have therefore conjectured that it would be contrived if this flatness was other than perfect.

An alternative $k = 0$ model of greater observational interest has a significant cosmological constant, so that $\Omega_m + \Omega v = 1$ (radiation being neglected for simplicity). This may seem contrived, but once k=0 has been established, it cannot change: individual contributions to Ω must adjust to keep in balance. The advantage of this model is that it is the only way of retaining the theoretical attractiveness of $k = 0$ while changing the age of the universe from the relation $H_0t_0 = 2/3$, which characterizes the Einstein–de Sitter model. Since much observational evidence indicates that $H_0t_0\simeq1$, this model has received a good deal of interest in recent years. For this case, the Friedmann equation is

$$\dot{a}^2 = H_0^2[\Omega_m a^{-1} + (1-\Omega_m)a^2]$$

+ Ω = 1. The accelerating effects of vacuum

that the photons emitted by the source pass with a uniform flux density through any sphere surrounding the source. We can now make a shift of origin, and consider the Robertson–Walker metric as being centered on the source; however, because of homogeneity, the comoving distance between the source and the observer is the same as we would calculate when we place the origin at our location. The photons from the source are therefore passing through a sphere, on which we sit, of proper surface area $4\pi[R_0 S_k(r)]^2$. However, redshift still affects the flux density in four further ways: photon energies and arrival rates are redshifted, reducing the flux density by a factor $(1+z)^2$; opposing this, the bandwidth $\mathrm{d}\nu$ is reduced by a factor $1+z$, so the energy flux per unit bandwidth goes down by one power of $1+z$; finally, the observed photons at frequency ν_0 were emitted at frequency $\nu_0(1+z)$, so the flux density is the luminosity at this frequency, divided by the total area, divided by $1+z$:

$$S_\nu(\nu_0) = \frac{L_\nu[(1+z)\nu_0]}{4\pi R_0^2 S_k^2(r)(1+z)}.$$

A word about units: L_ν in this equation would be measured in units of W Hz^{-1}. Recognizing that emission is often not isotropic, it is common to consider instead the luminosity emitted into unit solid angle—in which case there would be no factor of 4π, and the units of L_ν would be W Hz^{-1} sr^{-1}.

The flux density received by a given observer can be expressed by definition as the product of the specific intensity I_ν (the flux density received from unit solid angle of the sky) and the solid angle subtended by the source: $S_\nu = I_\nu\ \mathrm{d}\Omega$. Combining the angular size and flux–density relations thus gives the relativistic version of surface-brightness conservation. This is independent of cosmology:

$$I_\nu(\nu_0) = \frac{B_\nu[(1+z)\nu_0]}{(1+z)^3}$$

where B_ν is surface brightness (luminosity emitted into unit solid angle per unit area of source). We can integrate over ν_0 to obtain the corresponding total or bolometric formulae, which are needed for example for spectral-line emission: The form of these relations lead to

$$S_{\mathrm{tot}} = \frac{L_{\mathrm{tot}}}{4\pi R_0^2 S_k^2(r)(1+z)^2}$$

$$I_{\mathrm{tot}} = \frac{B_{\mathrm{tot}}}{(1+z)^4}.$$

the following definitions for particular kinds of distances: angular-diameter distance is

$$D_{\mathrm{A}} = (1+z)^{-1} R_0 S_k(r)$$

luminosity distance is

$$D_{\mathrm{L}} = (1+z)\ R_0 S_k(r).$$

Angular-diameter distance versus redshift is illustrated in figure 4.

The last element needed for the analysis of observations is a relation between redshift and age for the object being studied. This brings in our earlier relation between time and comoving radius (consider a null geodesic traversed by a photon that arrives at the present):

$$c\ \mathrm{d}t = R_0\ \mathrm{d}r/(1+z).$$

So far, all this is completely general; to complete the toolkit, we need the crucial input of relativistic dynamics, which is to give the distance–redshift relation.

Distance–redshift relation

The general relation between comoving distance and redshift was given earlier as

$$R_0\ \mathrm{d}r = \frac{c}{H(z)}\ \mathrm{d}z = \frac{c}{H_0}[\Omega_\nu + \Omega_{\mathrm{m}} a^{-3} + \Omega_{\mathrm{r}} a^{-4} - (\Omega - 1)a^{-2}]^{-1/2}\ \mathrm{d}z.$$

For a matter-dominated Friedmann model, this means that the distance of an object from which we receive photons today is

$$R_0 r = \frac{c}{H_0}\int_0^z \frac{\mathrm{d}z'}{(1+z')(1+\Omega z')^{1/2}}.$$

Integrals of this form often arise when manipulating Friedmann models; they can usually be tackled by the substitution $u^2 = k(\Omega{-}1)/\Omega(1{+}z)$. This substitution produces Mattig's formula, which is one of the single most useful equations in cosmology as far as observers are concerned:

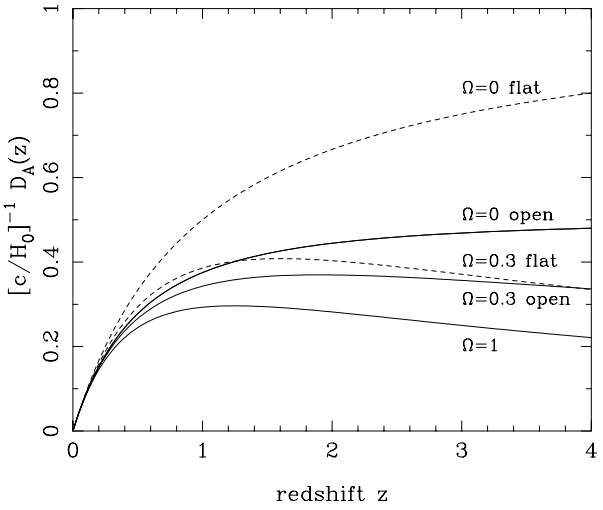

Figure 4. A plot of dimensionless angular-diameter distance versus redshift for various cosmologies. Solid curves show models with zero vacuum energy; dashed curves show flat models with $\Omega_{\mathrm{m}} + \Omega_v = 1$. In both cases, results for $\Omega_{\mathrm{m}} = 1,0.3,0$ are shown; higher density results in lower distance at high z, owing to gravitational focusing of light rays. Reproduced from *Cosmological Physics* (Cambridge University Press).

$$R_0 S_k(r) = \frac{2c}{H_0} \frac{\Omega z + (\Omega - 2)[(1 + \Omega z)^{1/2} - 1]}{\Omega^2 (1 + z)}.$$

There is no such compact expression if one wishes to allow for vacuum energy as well. The comoving distance has to be obtained by numerical integration of the fundamental $\mathrm{d}r/\mathrm{d}z$, even in the $k = 0$ case. However, for all forms of contribution to the energy content of the universe, the second-order distance–redshift relation is identical, and depends only on the deceleration parameter:

$$R_0 S_k(r) \simeq \frac{c}{H_0} \left(z - \frac{1 + q_0}{2} z^2 \right).$$

The sizes and flux densities of objects at moderate redshift therefore determine the geometry of the universe only once an equation of state is assumed, so that q_0 and Ω_0 can be related. At larger redshifts, this degeneracy is broken, and accurate measurements of the distance–redshift relation can in principle determine the parameters Ω_m, Ω_v etc independently.

Recent observations

NASA's Far Ultraviolet Spectroscopic Explorer (FUSE) satellite has given astronomers a glimpse of the ghostly cobweb of helium gas left over from the Big Bang, which underlies the universe's structure. The helium is not found in galaxies or stars but spread thinly through space. The observations help confirm theoretical models of how matter in the expanding universe condensed into a web-like structure pervading all the space between galaxies. The helium traces the architecture of the universe back to very early times. This structure arose from small gravitational instabilities seeded in the chaos just after the Big Bang.

Outstanding issues

As outlined above, the basic isotropic models of relativistic cosmology depend on four main parameters: the present rate of expansion and the present contributions to the total density of non-relativistic matter, ultrarelativistic matter and vacuum. The appearance of distant objects depends on these numbers, so in principle it is possible to determine these parameters, and also to investigate the weakest class of non-standard cosmologies—in which there may exist additional contributions to the density, with more exotic equations of state. All such possibilities can be investigated empirically within the framework of FRW models.

A deeper issue is to ask whether the basic assumption of isotropy and homogeneity is valid, and if so, why this should be. Studies of large-scale structure and anisotropies in the microwave background suggest that deviations from the Robertson–Walker metric are limited to fractional perturbations at about the 10^{-5} level, so the basic metric seems a good zero-order model. However, the existence of a particle horizon that is small at early times means that it is a major surprise to find the universe to be nearly homogeneous over regions that have only recently come into causal contact. This is one of a number of peculiarities in the standard model that cry out for explanation: like the basic fact of expansion and the near-perfect flatness, these are puzzles of the initial conditions that require explanation by a more complete theory, such as INFLATION.

Lastly, there are a number of peculiar features which relate to our status as observers. Unless $\Omega = 1$, we live near a special time—at which the contributions to the Friedmann equation from spatial curvature or vacuum energy are comparable with that of non-relativistic matter. There exists a body of ideas under the heading of the 'ANTHROPIC PRINCIPLE' which attempt to quantify the selection effects imposed by the need for intelligent observers. In some cases, these arguments are relatively uncontroversial: we should not be surprised that the universe is now roughly as old as a typical star, since stars are needed to make the heavy nuclei needed for interesting chemistry. Whether such reasoning explains all the features of the observed universe is likely to remain controversial. However, at a practical level, the standard isotropic cosmological models provide a context within which this difficult debate can at least be conducted with confidence.

Web update (31 July 2002)

A team of 27 astronomers led by Professor George Efstathiou of the University of Cambridge has published strong evidence for the existence of dark energy using the clustering pattern of 250 000 galaxies in a large volume of the universe surveyed with the Anglo–Australian Telescope at Siding Spring in New South Wales, Australia. By comparing the structure in the universe now, some 15 billion years after the Big Bang, with structure observed in the cosmic microwave background radiation, which preserved information about what the universe was like when it was only 300 000 years old, the Anglo–Australian team could apply a simple geometrical test to elucidate the composition of the universe. Their results show that the universe is full of vacuum energy, completely consistent with the earlier supernovae results.

Christopher Kochanek of the Harvard–Smithsonian Centre for Astrophysics in Cambridge, Massachusetts and Neal Dalal of the University of California, San Diego have used radio telescopes and gravitational lensing to search for cold dark matter. They have studied seven galaxies, each magnified by four nearer ones. Because each lensing galaxy is in a slightly different position, the researchers got four different images of each of the seven distant galaxies. The four images should have been

identical. But each is actually slightly different. The difference was enough to have been caused by the kind of clumps of dark matter around lensing galaxies that mathematical models predict.

Cosmology: A Brief History

Cosmology is the branch of astronomy that deals with studies of the large-scale structure of the universe. Observationally it requires data on the most remote objects while theoretically it demands the largest possible extrapolations of the basic laws of physics. Despite these severe constraints, cosmology has of late emerged as a very important branch of science where predictions can be made and tested.

When did modern cosmology begin? Indeed, one should go back to Isaac NEWTON, and his correspondence with Richard Bentley from 10 December 1692, to 17 January 1693 (see Whiteside 1976). It is interesting to read Newton's attempts to construct the model of a homogeneous and isotropic but static universe and his realization that it is unstable. Later attempts within the Newtonian framework, before relativity came on the horizon, were by C Neumann and H Seeliger during 1895–1896. In 1934, W H McCrea and E A Milne demonstrated how Newtonian ideas of gravitation and dynamics can be suitably adapted to give standard models of relativity.

The advent of the GENERAL THEORY OF RELATIVITY in 1915 offered a possible resolution of the conflicts which were beginning to surface between the Newtonian laws of dynamics and gravitation and SPECIAL RELATIVITY. General relativity linked the phenomenon of gravitation to the geometry of space and time. Only 2 years after he proposed the theory, ALBERT EINSTEIN made a bold attempt to apply it to construct a model of the entire universe.

Like Newton, Einstein also found that a static model was not permitted by his 1915 equations of relativity and introduced the so-called COSMOLOGICAL CONSTANT, λ, which implied (in the Newtonian approximation) a repulsive force that varied directly with distance. The static model that emerged required the universe to be closed. Einstein felt that the emergence of such a model was a demonstration of a unique and consistent relationship between spacetime geometry and the matter contents of the universe.

However, a paper by W DE SITTER in the same year demonstrated that the model was not unique. de Sitter found a model universe which was empty but expanding. Although it was considered esoteric at the time, this model has played a key role in cosmology on a number of later occasions.

In the second decade of this century, there was no systematic study of galaxies, although, by 1914, observers of diffuse nebulae, like V M Slipher, had reported nebular shifts, mostly redshifts, that indicated a radial recessional motion of these nebulae. However, despite these findings, the general belief in a static universe was quite strong and de Sitter's solution was treated more as a curiosity. Indeed, in 1922–1924, A Friedmann and later in 1927 (independently) Abbé Lemaître obtained models of the expanding universe for which the cosmological constant was not required, but these were also ignored by Einstein and others.

Meanwhile, understanding of the universe on the observational front was also growing. In 1924 E P HUBBLE had established, through the use of Cepheid variable stars, that the Andromeda Nebula is so far away that it has to be extragalactic. Indeed in the next few years the existence of extragalactic nebulae as galaxies in their own right began to be established.

However, it was the announcement of the velocity–distance relation of these nebulae by Hubble in 1929 that turned the tide in favor of these models. For, after a careful analysis of data on nebular redshifts, Hubble arrived at what is today known as 'HUBBLE'S LAW', namely that the radial velocity of a typical galaxy away from us is proportional to its distance from us. More exactly, the data show that the redshift of a galaxy increases with its faintness. If the redshift is interpreted as Doppler shift and faintness as due to distance, then Hubble's law follows. Although there might be other interpretations of the data, all cosmological models had to take cognizance of this basic fact about the universe. Indeed it was later realized that in his 1927 paper Lemaître had predicted a linear velocity–distance relation of this kind.

Thus, soon after Hubble's law became accepted, Einstein saw that a static model was unrealistic and abandoned the cosmological constant as the 'greatest blunder' in his life. There were others, however, who thought otherwise and, even today, this constant continues to feature in cosmological literature. The reader interested in knowing who did what and when in those early days may wish to see the historical account by North (1965).

The big bang models

The assumption of homogeneity and isotropy allows the cosmologist to define a 'cosmic time'. The spatial sections at a given cosmic time are supposed to be homogeneous and isotropic. H P Robertson in 1935 and A G Walker in 1936 independently worked out the most general line element describing such a spacetime. Taking any observer as the local origin of spherical polar coordinates (r, θ, ϕ) and t for the cosmic time, the Robertson–Walker line element is given by

$$\mathrm{d}s^2 = c^2\,\mathrm{d}t^2 - S^2(t)\left[\frac{\mathrm{d}r^2}{1-kr^2} - r^2(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)\right]. \quad (1)$$

The function $S(t)$ is the scale factor mentioned earlier: its increase with time signifies the expansion of the universe. The constant k in the above is a parameter specifying whether the space t = constant is of positive ($k = +1$), negative ($k = -1$) or zero ($k = 0$) curvature.

The simplest FRIEDMANN model is the Einstein–de Sitter model jointly advocated by Einstein and de Sitter (1932) which has $k = 0$. For pressure-free matter (often called dust) this model has $S \propto t^{2/3}$.

That the geometrical features of the model are linked to its physical matter contents is demonstrated by the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

different behavior of these models for different matter density ρ. Thus we define the following quantities:

$$H(t) = \frac{\dot{S}}{S} \qquad \rho_c = \frac{3H^2}{8\pi G} \tag{2}$$

as the HUBBLE CONSTANT and the critical density at epoch t. We will denote their values at the present epoch t_0 by suffix zero. The density parameter is defined by

$$\Omega = \frac{\rho}{\rho_c}. \tag{3}$$

Then for the Friedmann solutions we have the following result: the universe is closed for $\Omega_0 > 1$ and open otherwise ($k = 0, -1$). Actually the case $k = 0$ is the marginally open case with $\Omega_0 = 1$; if the density exceeds ρ_c the universe is of the closed type. This is why the density ρ_c is called the closure or critical density.

In all models the scale factor was zero at some epoch in the past, commonly called the big bang epoch. At this epoch the curvature of spacetime was infinite and so was the density of matter and radiation in the universe. What about the future behavior of the universe? There the answer depends on the geometry of space. In the open models the universe expands for ever, with the scale factor going to infinity. In the closed models the scale factor attains a maximum value before decreasing back to zero.

In the above argument it is assumed that the matter in the universe is in the form of dust. This is a reasonable approximation at present when pressures are small and matter density far exceeds the density of radiation. However, one can show that

$$\rho_{\text{matter}} \propto S^{-3} \qquad \rho_{\text{radiation}} \propto S^{-4} \tag{4}$$

so that, at a sufficiently early epoch when S was small enough, the radiation term dominated over the matter term. This of course does not alter the earlier conclusion about the existence of the big bang epoch; in fact we now conclude that the universe was infinitely hot at that epoch.

In the Robertson–Walker spacetimes, the redshift is simply related to the scale factor. Calculation shows that a source with redshift z is being observed at an epoch when the scale factor of the universe was $(1+z)^{-1}$ times its present value. Observations at the present epoch indicate that matter density is at least $\sim 10^3$ times the radiation density. Thus we can estimate that the universe was radiation dominated at epochs prior to that of redshift $\sim 10^3$.

With the realization that the basic Friedmann models give an adequate description of the expanding universe, there have been many developments in cosmology in the last five decades that are based on these models. These developments may broadly be divided into investigations of (a) large-scale structure, through observations of discrete sources, (b) early history of the universe, through observations of relics, (c) evolution of the universe from particles to galaxies, (d) basic physical laws operating in the extreme conditions a few moments after the big bang, and (e) alternative cosmologies. We will briefly outline a few historical results.

Observations of discrete sources

A relativistic cosmological model uses curved spacetime and as such there are effects of non-Euclidean geometries that may, in principle, be observable. This was the expectation which prompted optical and radio astronomers of the 1950s and 1960s to push their observing capabilities to the limit. By observing the distributions of discrete source populations (galaxies, quasars, radio sources, x-ray sources, etc) the cosmologist hoped to find which of the various theoretical models came closest to reality.

The observational tests included (i) the measurement of Hubble's constant, (ii) the extension of Hubble's law to galaxies of large redshifts, (iii) the counts of galaxies and radio sources out to larger and larger distances, (iv) the angular diameter–redshift relation and (v) the relationship of surface brightness of a galaxy to its redshift. For details of these cosmological tests see recent textbooks and review articles, e.g. Sandage (1988) and Narlikar (1993).

The trend of such studies has shifted, however, from determining the geometry of the universe to determining how the discrete sources evolve. These studies are expected to tell us about the evolution of the physical environment of the universe, but so far no clear picture has emerged amidst a series of parameter-fitting exercises.

A key measurement that continues to be controversial is that of Hubble's constant. Hubble originally obtained the value of 530 km s^{-1} Mpc^{-1}, but in retrospect we find that there were several systematic errors in his measurements. For a long time, as the value of the constant steadily came down, there was continuing controversy about its true value, which was believed to lie between 50 and 100 km s^{-1} Mpc^{-1}.

Even today there are several calibration problems. However, it is only now that a clear appreciation of various practical issues is emerging, and different approaches are beginning to converge to a value of H_0 somewhere between 55 and 70 km s^{-1} Mpc^{-1}.

Relics of the early universe

The BIG BANG THEORY hinges on the fact that, at a time $t = 0$, the universe came into existence in a singular event. Thus no physical description of the original event is possible, although physical theories can examine the subsequent behavior of the universe. One of the early attempts to go close to the big bang epoch was made in the late 1940s by GEORGE GAMOW, who appreciated the fact that the early universe was radiation dominated, that is, its contents were made up of photons and other particles which were mostly relativistic in their energies. Thus, one could approximate the equation of state by pressure $p = \frac{1}{3}\rho$, both p and ρ being dependent on temperature as its fourth power, as for radiation in thermal equilibrium. Gamow and his collaborators Ralph Alpher and Robert Herman worked out the physics of the universe when it was around 1–200 s old. (A paper in 1948 by Alpher, H Bethe and Gamow on this topic led to it being called the 'α–β–γ' theory!)

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Gamow had hoped to demonstrate that, in the high temperatures prevailing in this era, particles such as neutrons and protons would be synthesized into heavier nuclei, thereby determining the chemical composition of the universe. In the end, this work was partly successful in that light nuclei such as deuterium, helium, etc could be made in the primordial soup, but not the heavier ones such as carbon, oxygen and metals. Later it became clear from the important work of Burbidge, Burbidge, Fowler and Hoyle in 1957 (referred to as the B^2FH theory) that these nuclei are made in stars. Nevertheless, the abundances of light nuclei worked out according to the modern version of Gamow's pioneering attempt show a broad agreement with the observed ones.

A further check on the early hot universe scenario was the discovery in 1965 of the COSMIC MICROWAVE BACKGROUND by Penzias and Wilson. Gamow, Alpher and Herman had predicted such a background as the relic of the early era, although the discoverers had been unaware of these results. In their 1948 paper Alpher and Herman had predicted a relic background with an estimated temperature of 5 K. Present big bang calculations, however, cannot estimate the temperature of the background: it has to be taken as a parameter prescribed by observations. It should be mentioned that in the early 1960s R H Dicke and his colleagues had independently arrived at the Gamow–Alpher–Herman prediction of relic radiation and were setting up a detector for the radiation when they were anticipated by Penzias and Wilson.

The most spectacular development of recent years has been the success of the COBE satellite in measuring the spectrum (in 1990) and small-scale anisotropy (in 1994) of the microwave background. The background shows a black body temperature of 2.7 K and is highly homogeneous, with temperature fluctuations $\Delta T/T \sim 6 \times 10^{-6}$.

The abundances of light nuclei and the microwave background, its spectrum and anisotropy have provided strong prima facie support for the big bang scenario. There were constraints and challenges too.

Evolution of structure in the universe

A major challenge in cosmology has been to demonstrate how, in the standard big bang model, first nucleons and leptons evolved out of more primordial particles and from them eventually the large-scale structures in the universe formed; all this in a manner consistent with the radiation fluctuations found by COBE.

Of particular interest in this work is the role of the inflationary phase first discussed independently by A Guth, K Sato and D Kazanas during 1980–1981. The basic idea is the following. The big bang universe was infinitely hot at $t = 0$, but its temperature dropped with time according to $t^{-1/2}$. In this process, the matter in it underwent a phase transition and its effect was, for a very brief period, to inflate the universe at an exponential rate, much like the old de Sitter universe. The changes in the spacetime vacuum generate a force that simulates the cosmological constant first introduced by Einstein. This is the force that 'drives' the universe so fast with an exponential growth at a time scale of around 10^{-36} s.

Most theories of structure formation rely on initial fluctuations as they evolve through INFLATION and their subsequent growth. The latter takes place through gravitational interaction and clustering. Here cognizance must be taken of the interaction of the growing lumps of inhomogeneities not only with the visible matter but also with DARK MATTER. In particular, the results are sensitive to the type of dark matter, 'cold' or 'hot' or a mixture of both.

Dark matter is the name given to matter that is not normally seen through any waveband of the electromagnetic radiation. It was FRITZ ZWICKY who in 1933, first pointed out the possible existence of the 'missing mass' in clusters of galaxies. However, it took nearly four decades for the astronomical community to catch up with him! In the 1970s, the studies of motions of clouds of neutral hydrogen showed that they were moving with near constant rotational speeds around a typical spiral galaxy, even if they were located at progressively larger distances beyond the visible mass of the galaxy. These flat rotation curves indicated that the mass $M(R)$ of a galaxy up to a distance R from its centre increases approximately in proportion to R even if R vastly exceeds the visible boundary of the galaxy.

Likewise, Zwicky's expectations about hidden mass in clusters were also borne out with the findings that the galaxies in a typical cluster were moving with such high speeds that if one uses the virial theorem for a relaxed cluster

$$2T + \Phi = \text{constant} \tag{5}$$

where T is the kinetic energy and Φ the gravitational potential energy, then one needs a lot of hidden mass to make up for the latter. What is this dark matter made of and how much of it exists in the universe? This important question has been hotly debated but remains unanswered.

The present cosmological model building has to take various constraints into account and, within the big bang framework, the need to resurrect the cosmological constant is being strongly felt. It is, however, correct to say that the model building exercise is yet to settle down to a well accepted set of parameters including the value of this constant.

Alternative cosmologies

From time to time there have been alternatives proposed to the big bang cosmology, although the majority of cosmologists have always believed in the validity of the latter. The STEADY STATE THEORY proposed in 1948 by H Bondi, T Gold and F Hoyle livened up the cosmological scenario by offering a clearly testable alternative. This cosmology had the spacetime geometry described by the model proposed by de Sitter in 1917, although the physical rationale was different. The discovery of the microwave background in 1965 robbed the theory of much of its

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

credibility. Other major initiatives in the field were the Brans–Dicke cosmology proposed by C Brans and R H Dicke in 1961, as a theory with its origins in Mach's principle, and the cosmology proposed by P A M Dirac in 1973, based on attempts to explain the very large dimensionless numbers that appear in cosmology and microphysics.

Lately, in 1993, the steady state theory has been revived in the modified form called the quasi-steady state cosmology (QSSC), by F Hoyle, G Burbidge and J V Narlikar.

Conclusions

As the observational details about the universe become more and more focused, the big bang cosmology becomes more and more constrained. For example, one long standing discrepancy has not yet been resolved: the ages of stars in some very old globular clusters are in the range 12–15 billion years, which is larger than the timespan of the standard model! This is another reason for reviving the λ term, for its inclusion can increase the age of the universe.

In the last analysis, what cosmological theory survives would depend on how the observational challenges are met. Unlike the situation at the start of this century, when there were hardly any cosmological parameters to constrain the theory, we now suffer from the embarrassment of riches. Let the fittest theory survive.

Crab Nebula (M1, NGC 1952)

A supernova remnant in the constellation Taurus, position RA $05^{h}\,34.5^{m}$, dec. $+22^{\circ}\,00'$. The supernova of AD 1054 that produced the nebula reached a magnitude of -6, visible in daytime. The nebula was discovered in 1731 by John Bevis and independently in 1758 by Charles Messier, prompting him to start compiling his list of objects that might be confused with comets. It was named by Lord Rosse for its superficial resemblance to a crab. The Crab is $6'$ by $4'$ in extent and of eighth magnitude. Its outer regions consist of twisting filaments of hydrogen expelled by the supernova, appearing red on photographs and traveling outward at over 1000 km s^{-1}. The inner region glows with the pale yellow light of synchrotron radiation triggered by electrons emitted by the Crab Pulsar at the center, the core of the star that exploded as a supernova. This inner region makes the Crab Nebula the best-known example of a plerion—a supernova remnant with a 'filled' center. The Crab emits strongly in radio waves (and has the radio designation Taurus A) and x-rays (Taurus X-1).

Crab Pulsar

The pulsar PSR 0531 + 21 (previously known as NP 0532), situated at the heart of the Crab nebula in Taurus. One of the first pulsars to be discovered, in 1968, and the first to be positively identified with a visible object. Known since 1948 as the powerful radio source Taurus A, the Crab nebula had been discovered in 1964 to be a powerful source of x-rays as well—the first to be optically identified beyond the solar system.

The discovery of the first pulsar (PSR 1919 + 21) by Jocelyn Bell (b. 1943) and Antony Hewish (b. 1924) at Cambridge in November 1967 was all the more remarkable because of its rapid pulse rate, with a period of only 1.337 s, and the one part in a million consistency with which this period was maintained. As further pulsars were discovered (more than 20 within a year), some were found to have periods of even less than a second. Such rapidly rotating sources implied that the objects were of very small size, and hence were of unprecedentedly high density. This led to considerable effort by physicists to devise a theoretical model which would provide a satisfactory explanation. The concept of super-dense neutron stars had been proposed as early as 1934 by Walter Baade (1893–1960) and Fritz Zwicky (1898–1974); they had also suggested that they might be associated with supernova explosions. In 1939 Zwicky suggested that the vast energy released in a supernova explosion might arise from the creation of a neutron star, and with remarkable foresight suggested that the Crab Nebula might contain such an object.

Foremost among the theorists considering the newly discovered pulsars was Thomas Gold (b. 1920) at Cornell University, New York, who published a paper in 1968 suggesting that a spinning neutron star was indeed the only possible mechanism that could explain such a rapidly pulsating object. The theory was virtually confirmed by the discovery of the Crab pulsar a few months later, with its dramatically short period of only 33.3 ms. The south-westernmost of a pair of stars visible near the center of the Crab nebula had been identified in 1942 by Zwicky and Rudolph Minkowski (1895–1976) as the most likely supernova remnant. Observations made in January 1969 at the Steward Observatory in Tucson, Arizona, confirmed that this sixteenth-magnitude star showed the same rapid fluctuations in brightness as the pulsar—the first optical identification of a radio pulsar. Only a few such optical/radio identifications are known, owing to their very low luminosity at optical wavelengths.

Subsequent observations have shown the Crab pulsar's rotation to be decelerating by 36.4 ns per day. This loss in rotational energy arises from its conversion into synchrotron radiation, which is emitted into the surrounding nebula along paths constrained by a strong dipolar magnetic field and gives rise to the lighthouse-like 'flashes' as the star rotates. Minkowski's suggestion that the neutron star is the power source of the nebula has thus been triumphantly vindicated. Measurements of the expansion of the nebula have confirmed its identification with a supernova explosion observed in AD 1054, indicating that this is one of the youngest pulsars yet discovered—hence its very rapid rotation.

As the most easily observable pulsar, and being active over much of the electromagnetic spectrum, the Crab pulsar has remained one of the most important targets of astrophysical research.

Crabtree, William (1610–44)

Instrument-maker and astronomer, born in Broughton, Lancashire, England, studied sunspots, made precise observations of the planets, including a transit of Venus. Crabtree collaborated with HORROCKS who predicted the transit. Horrocks described his friend Crabtree as 'a man who has few superiors in mathematical learning' and described how awestruck Crabtree had been on perceiving the little disc of Venus moving against the face of the Sun: 'rapt in contemplation he stood, motionless, scarce trusting his senses through excess of joy'.

Cramér–Rao Limit (or minimum-variance bound)

When it is difficult to calculate the variance (statistical error) of a parameter, the more readily calculated Cramér–Rao limit in statistics can be used as an estimate. The Cramér–Rao limit is in fact a lower bound to the variance but it is often about the same size. The reality of this assumption has to be investigated case by case, e.g. by Monte Carlo simulations.

Crater Constellation

(the Cup; abbrev. Crt, gen. Crateris; area 282 sq. deg.) A southern constellation which lies to the south-west of Virgo, and culminates at midnight in mid-March. It represents the cup of the god Apollo in Greek mythology (see Corvus). Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A small, rather inconspicuous constellation, the brightest stars in Crater are δ Crateris, magnitude 3.6, and γ Crateris and α Crateris (Alkes), both magnitude 4.1, which form an isosceles triangle pointing away from Virgo. γ is a binary, having a magnitude 9.5 companion, separation 5.2″. There are no bright star clusters, nebulae or galaxies in Crater.

Craters

Craters are bowl-shaped cavities which have been formed by an explosion. On planetary bodies, the few examples of past or present volcanism (Mars, Venus, Io) are not of the explosive type. Therefore, nearly all craters on PLANETARY SURFACES result from the impact of a METEOROID at very high speeds (tens of km s^{-1}). PLANETARY EXPLORATION has demonstrated that impact craters are ubiquitous features of the geology of solid solar system bodies. For most objects, internally driven evolution (tectonics, volcanism) has stopped after a few million to a few hundred million years. Impact cratering at all scales has therefore been a major factor for the evolution of planetary surfaces.

First, a family portrait of craters throughout the SOLAR SYSTEM will be drawn, with their striking similarities and intriguing differences. We will present the early controversies on lunar craters, the only such planetary features which can be seen with the naked eye, and the evidence from which lunar craters as well as nearly all other craters in the solar system are now recognized as impact features instead of volcanic craters.

In a further section, the origin of impacting bodies will be discussed. The evolution of the impact rate with time is closely related to the formation process of the solar system (see SOLAR SYSTEM: FORMATION). Our understanding of collision processes in the solar system has recently much improved with the advent of chaotic dynamical models.

We will then discuss the physics of impact cratering. The formation of craters is ruled by relatively simple scaling laws over an extremely wide range of impacting masses. The evolution of large craters is strongly influenced by gravity. At the higher end of the size range, the relaxation of the planetary crust modifies the crater shape. Understanding these crater formation and evolution processes is essential when attempting to derive the ages of solar system surfaces from the cratering record.

Finally, the consequences of crater formation at all scales on the evolution of a planetary surface will be examined. They range from the formation of major impact basins several thousand kilometers in diameter to thorough modifications of the mineralogy and texture of surface soils (or regoliths). Perhaps the most dramatic cratering event of all may have been the giant impact of a Mars-sized body on the Earth which is now considered to be at the origin of the formation of the Moon.

Craters in the solar system

The most direct evidence that high-velocity objects impact planetary bodies is the observation of a shooting star, which shines brightly due to its very high temperature upon atmospheric entry. The typical mass of these particles is a few milligrams. In the nineteenth century, METEORITES with masses of a few hundred grams to several tonnes were identified as extraterrestrial objects. The other line of evidence can be traced back to the observation by GALILEO of round features at all scales on the lunar surface, the lunar craters and basins (see MOON). Up to the middle of the twentieth century the origin of these features was controversial, as they were attributed either to volcanic activity or to impact processes. The matter was finally laid to rest with the Apollo program. In the mean time, the best preserved terrestrial impact crater had been discovered in northern Arizona (of course, it was known for centuries by the Navajos): METEOR CRATER, with its diameter of 2 km and its depth of more than 300 m, is a very young feature formed 40 000 years ago (figure 1). It shows a striking similarity with bomb craters, with its bowl shape and slightly raised rim. Indeed, impact and explosion cratering are closely related, and a lot has been learned about the physics of cratering from the near-surface nuclear tests of the 1950s and early 1960s.

Figure 1. Meteor Crater, near Flagstaff in northern Arizona, is the youngest and best preserved large impact crater on the Earth, with a size of 2 km. It was formed by the impact of an iron meteor a few tens of meters in diameter. The similarity with craters generated by explosions is striking, with a bowl shape and raised rim.

The extraordinary adventure of planetary exploration during the last 40 years has demonstrated the ubiquitous character of impact cratering in the solar system. Indeed, the first impression given by the first Mars fly-bys was that it was, somewhat disappointingly, just a larger version of the Moon. These observations happened to cover the older, southern hemisphere of the planet which is indeed dominated by impact craters. When the Mariner 9 orbiter finally obtained a global coverage, it revealed the tremendous volcanoes and canyons which characterize the Tharsis region. The large cavities at the top of these volcanoes have been formed by collapse, not by an explosion, and are therefore calderas, not craters. The PIONEER and VOYAGER MISSIONS to the systems of outer planets have observed enormous impact features, such as the Valhalla basin on GANYMEDE (figure 2). At the other end of the solar system, MERCURY was revealed as a near twin to our Moon, its surface being pocked with craters of all sizes. Only 50% of the surface of Mercury has been imaged, so that surprises cannot be excluded once the other hemisphere is observed. More recently, close-range observations of ASTEROIDS showed craters with sizes up to 30% of the diameter of the body (figure 3).

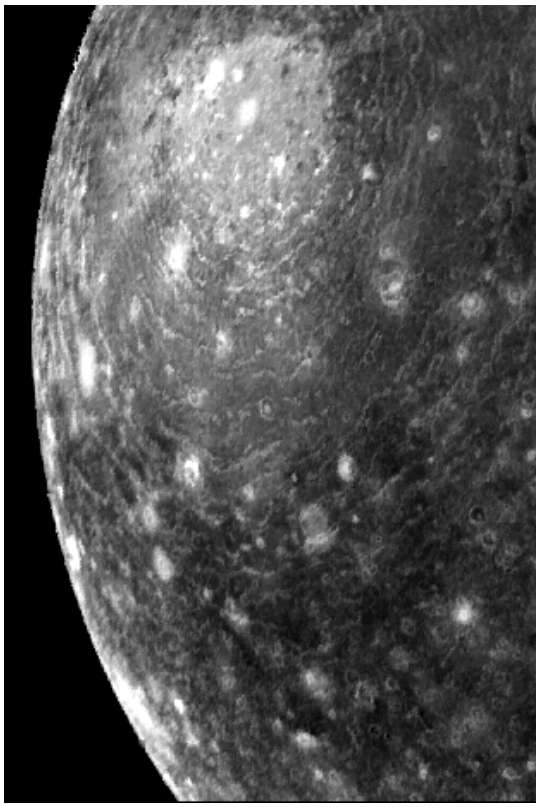

Figure 2. The Valhalla basin is an impact structure nearly 2000 km in diameter on Callisto, the outer large satellite of Jupiter. The small vertical extent and concentric rings reveal the importance of relaxation processes in the icy lithosphere. This structure is pockmarked by later impacts which saturate the surface.

Figure 3. This image of Ida, a 40 km sized asteroid in the main belt, was obtained by the Galileo spacecraft on its way to Jupiter. The global shape of the asteroid is indented by major impact craters, while smaller craters are ubiquitous on the surface.

The wealth of observations from planetary missions has also shown that several planetary bodies exhibit much smaller densities of impact craters. This is the case for Venus, Io, Europa and icy satellites such as Enceladus (satellite of Saturn) or Miranda (satellite of Uranus). The example of the Earth suggests that this situation arises when resurfacing processes have erased all but the latest impact craters, i.e. when the surface is younger than a few hundred million years. The cratering record is therefore clearly linked with the age of the surface, which leads to a discussion of the origin of impacts in the solar system.

The history and characteristics of impacts in the solar system

Much of what we know about the time evolution of cratering comes from the study of lunar samples gathered by the Apollo and Luna programs in the early 1970s. The potassium–argon radioisotopic chronometer is reset by shock events, as the daughter product, argon, is a noble gas which is expelled under high pressures. These analyses provided the first absolute ages of major impact events on the Moon, such as that which formed the IMBRIUM BASIN, 3.8 billion years ago. The age of lunar mare, which provided clean plates for registering impacts from 4 to 3 billion years ago could be determined from the rock formation ages of lunar basalts (uranium–lead and rubidium–strontium chronometers). Since 1970, the advent of chaotic dynamics has much improved our understanding of the evolution of protoplanetary swarms during the formation of the solar system. These theories also provided a satisfactory model of the transfer of asteroids or asteroidal fragments to the inner solar system by planetary perturbations. From these various sources of information, there is now a wide consensus on the following scenario:

(a) The condensation of the solar nebula resulted in the formation of a very large number of small bodies, the planetesimals in the inner solar system and the cometesimals in the outer solar system.
(b) The planetary embryos first grew by direct collisions, which resulted in a few million years of extremely heavy bombardment.
(c) Once the direct feeding zones were cleaned up, gravitational perturbations induced further collisions or near encounters between the surviving objects. The remaining primordial population of small bodies was then progressively cleaned up by collisions with planets or ejection in the OORT CLOUD. This phase, the accretionary tail, lasted more than 500 million years according to the ages of lunar basins. It left three major reservoirs: the Oort cloud, corresponding to cometesimals ejected at large distances by the giant planets, the main belt of asteroids, where the accretion of a planet was prevented by the proximity of the proto Jupiter, and the KUIPER BELT of cometesimals, where the density was too low to form a planet.
(d) During the remaining 4 billion years, collisions in the main belt, planetary and stellar perturbations have resulted in a steady state flux of secondary objects, represented nowadays by near-Earth asteroids (from the main belt), short-period comets (from the Kuiper belt) and long-period comets (from the Oort cloud). The relative contribution of comets and asteroids to

the impact rate is highly uncertain. It is expected to depend on the distance to the Sun, with comets representing up to one-third of the impacts on the Earth and Moon. On the Moon, this constant impact rate corresponds to the formation of a kilometer sized crater every 30 000 years. On the Earth, it is doubled as impactors are focused by the strong gravitational field, but this also makes the craters smaller. The 2 km wide Meteor Crater, formed 40 000 years ago, is therefore quite typical taking into account the large surface fraction covered by oceans.

The impact velocities depend strongly on the distance to the Sun and on the source region. As a simple rule, the relative velocity of an impactor with a planetary body is a major fraction of its orbital velocity, long-period comets having the largest impact velocity. For the Earth–Moon system, with its orbital velocity of 29.8 km s^{-1}, the typical impact velocity is 20 km s^{-1}. For Mercury (50 km s^{-1} orbital velocity) it is likely to be more than 30 km s^{-1}. In the main belt, a major source region, the relative velocities are less than 10 km s^{-1} for asteroidal fragments and more than 10 km s^{-1} for comets, which have a much larger eccentricity. The planetocentric velocity of satellites (1 km s^{-1} for the Moon) only becomes a factor for the inner satellites of Jupiter (Io: 17 km s^{-1}).

The mass distribution of impacting bodies is not modified by gravitational perturbations. It is therefore expected to be very similar for objects from the same source region throughout the solar system. As a simple approximation, the flux of objects above a given mass is inversely proportional to the mass, with a steeper dependence at small masses and a flatter dependence at large masses. The dependence of cometary and asteroidal contributions with heliocentric distance is still uncertain.

The physics of impact cratering

The impact cratering process is closely related to the formation of craters by explosions. This relationship can be inferred from the comparison between impact velocities (5 to 30 km s^{-1}) and the highest detonation speed of chemical explosives (7 km s^{-1}). Therefore, an impactor delivers an energy per kilogram which is in the range of those dissipated by high-yield explosives. All non-grazing impacts are extremely inelastic, forming a bubble of gas with an initial temperature of several 10 000 K. At these very high velocities, it is the expansion of this bubble of gas which results in the formation of the crater, once again quite similarly to a chemical or nuclear explosion.

As the shock wave expands, it incorporates an increasing mass of material, which slows down its velocity. The initial expansion velocity is related to the impact velocity, hence is higher than the speed of sound. During this hypersonic phase, the shock wave is at the outer edge of the expanding cavity. Once the expansion has slowed below the speed of sound, the compression wave expands faster than the edge of the cavity. These P-waves eventually propagate far from the impacts. Impact events are therefore a source of low-magnitude seismic activity.

With a given impact velocity, the distance at which the specific energy per kilogram drops below a given value is proportional to the radius of the impactor. As an example, at 10 radii from the impact, the cavity corresponds to 500 times the impacting volume, hence a mean distributed energy 1/500 the impact energy, irrespective of the scale. Assuming a simple equipartition between kinetic and thermal energies, the expanding and decelerating shock wave defines four major zones:

(a) Very close to the impact, the energy per kilogram is higher than the vaporization energy of the material. The mass of gas formed is similar to the mass of the impactor at velocities of 20 km s^{-1}.
(b) Farther out, the energy per kilogram is higher than the melt energy. The mass of liquid is typically 10 to 20 times the mass of the impactor at 20 km s^{-1}.
(c) At a distance from the impact which is proportional to the size of the impactor and depends on the specific cohesive energy of the material, the shock wave becomes unable to fragment the material. This distance defines the radius R_S of the transient cavity, the so-called 'strength crater', within which the material is set loose from the substrate.
(d) Outside the transient cavity, the propagating shock wave may generate non-destructive fractures and shock pressure effects.

At any stage of the expansion, the velocity of the ejecta is expected to be similar to that of the shock wave. The slowest ejecta, coming out from the edge of the transient cavity, are therefore expected to leave at a velocity V_S which is proportional to the square root of the cohesive energy of the material. This simple scaling law for ejecta velocities has been experimentally tested for materials as different as basalt and pumice sand. The parabolic trajectory of ejecta is then determined by the surface gravity of the impacted body. For the slowest ejecta, the travelled distance is V_S^2/g, which defines the gravity radius R_g. If the strength radius R_S is smaller than R_g, most ejecta end up far from the crater. Its final morphology is then that of the transient cavity. For such 'strength craters', the observed depth to diameter ratio is about 0.4, close to the 0.5 value which would correspond to our simplistic model of a spherically expanding shock wave (the difference results from the enhanced disruption of material near the free surface).

The final shape of larger craters is dominated by gravity. When R_S is larger than R_g, ejecta are pulled back into the raised rims typical of large lunar craters and partially fill the impact cavity. Most of the energy is now expended as gravitational potential energy, so that the size of gravity craters does not depend on the cohesive strength of the material. The transition occurs at very small scales for non-cohesive material in a strong gravity field. As an example, R_g is only 1 m for the lunar regolith. For a rocky substrate, or for low-gravity bodies such as asteroids, this transition is on a kilometer scale. As material falls back into the transient cavity, it is not surprising that gravity craters are much shallower than strength craters, with depth to

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

diameter ratios as low as one to five. Furthermore, lateral transport of the loose rim material tends to flow back into the crater, so that gravity craters gradually fade out with a lifetime proportional to the square of their size.

For the largest craters (more than 20 km in diameter on the Moon), the lithosphere cannot support the initial crater topography against gravitational forces. Partial collapses lead to the formation of complex craters, characterized by faults, slumped walls and terraces. Before these long-term relaxation processes, a rebound in the lithosphere forms a central peak. This is similar to the impact of a rain drop in a puddle, after which a small droplet is shot back. At scales of more than a few hundred kilometers, impact craters are named basins, around which the propagating shock wave generates concentric rings. The readjustments of the crust explain the relatively small vertical extent of very large impact structures (up to 10 km for lunar basins, even less for basins on icy satellites). The northern regions of MARS represent a very specific case, as there are large amounts of subsurface ice at increasing depths towards the south. The fluidized ejecta from craters in the right size range generate 'splash craters' characterized by a sharp outer boundary of the lobate ejecta blanket.

At the upper end of the size range, major cratering events can occur at a scale similar to the size of the impacted body itself. The propagation of the shock wave can no longer be considered in the infinite planar surface approximation, but must be analysed in three dimensions, taking into account possible reflections at the surface. Shock wave focusing may be responsible for the irregular terrains observed in regions antipodal to major impacts on several solar system bodies, such as Mercury. Experimental simulations have been done at a scale of less than 10 cm which showed that the maximum crater size beyond which complete fragmentation occurs is about 40% of the size of the impacted body. The cratering record in the solar system is a remarkable demonstration of the validity of scaling laws for impact cratering: subcritical craters have indeed been observed for a wide range of solar system bodies, in particular Phobos (25 km in size), the largest of the two satellites of Mars (see PHOBOS AND DEIMOS), with its large crater Stickney (9 km in diameter), but also asteroids such as Ida and Mathilde and icy satellites such as Mimas. In the case of Phobos, linear grooves originating from Stickney and propagating over the whole surface suggest that global fracturation has occurred, stopping just short of fragmentation. Models show that in the main belt of asteroids, all objects smaller than about 200 km have a lifetime shorter than the age of the solar system. Fragmentation does not necessarily means destruction: if the body is large and/or weak, its self-gravitational energy is much larger than its cohesive energy. In such a case, the fragments will reassemble in 'rubble piles' with an equilibrium ellipsoidal shape if the body is rotating. These objects are expected to represent a large fraction of asteroids of intermediate sizes. The most dramatic cratering event in the inner solar system was probably the giant impact of a Mars-sized body with the Earth which is now widely considered to be responsible for the formation of the Moon.

The simple proportional scaling between the size of the impacting body and the size of the crater in the strength regime is very well substantiated by experiments. The dependence on the impacting velocity is much more complex. The analogy with explosion craters led to the hypothesis that the volume of the crater is simply proportional to the energy of the impact, hence the square of the impact velocity. This assumes correctly that the formation of the gas bubble can be considered as a point source when compared with the size of the crater. This 'energy scaling' assumption seemed consistent with the extreme inelastic character of the crater formation process. Experimental results in weakly cohesive material suggested a dependence on momentum, not energy, hence a volume which is proportional to the impact velocity. Recent results all lie in the range between these two models. The model dependent variation with velocity is a major problem when attempting to adapt the well calibrated lunar production curve to determine absolute crater production rates on other solar system bodies: as we have seen, impact velocities can be substantially higher (Mercury) or lower (asteroids, icy satellites) than on the Moon.

Once formed on the surface of a solar system body, craters are not eternal. Geological processes and erosion can erase the cratering record. On the Earth, most of the surface is renewed on time scales of millions of years. On Mars, there is a striking difference in terms of cratering record between the old southern hemisphere and the northern hemisphere, which remained geologically active for more than 3 billion years. Even on inactive bodies devoid of atmosphere, such as the Moon or Mercury, two major external processes are at work: impact obliteration and impact erosion. Obliteration occurs when the formation of a new crater wipes out all or part of a pre-existing crater. The lifetime against obliteration increases for large craters, which survive all but the biggest local impacts. This process was dominant during the accretionary tail, when the flux of impactors was very large. Impact erosion results from the progressive modification of the shape of the crater by small impacts, which are very numerous (typically 1000 times more frequent for a size which is 10 times smaller than the original impactor). Erosion processes are strongly dependent on gravity: in low-gravity environments, such as small satellites or asteroids, ejecta from small impacts will be removed from the vicinity of the crater, leading to a simple 'sand-blasting' erosion process. In a significant gravity field, such ejecta travel preferentially downslope, at a rate which is proportional to the slope angle and inversely proportional to the gravity. Highs (the rim) and lows (the bottom of the crater) tend to relax towards the horizontal quite similarly to the dissipation of a heat pulse, hence the lifetime is proportional to the square of the crater diameter. These old craters with subdued topography are visible close to the terminator, where they saturate the surface.

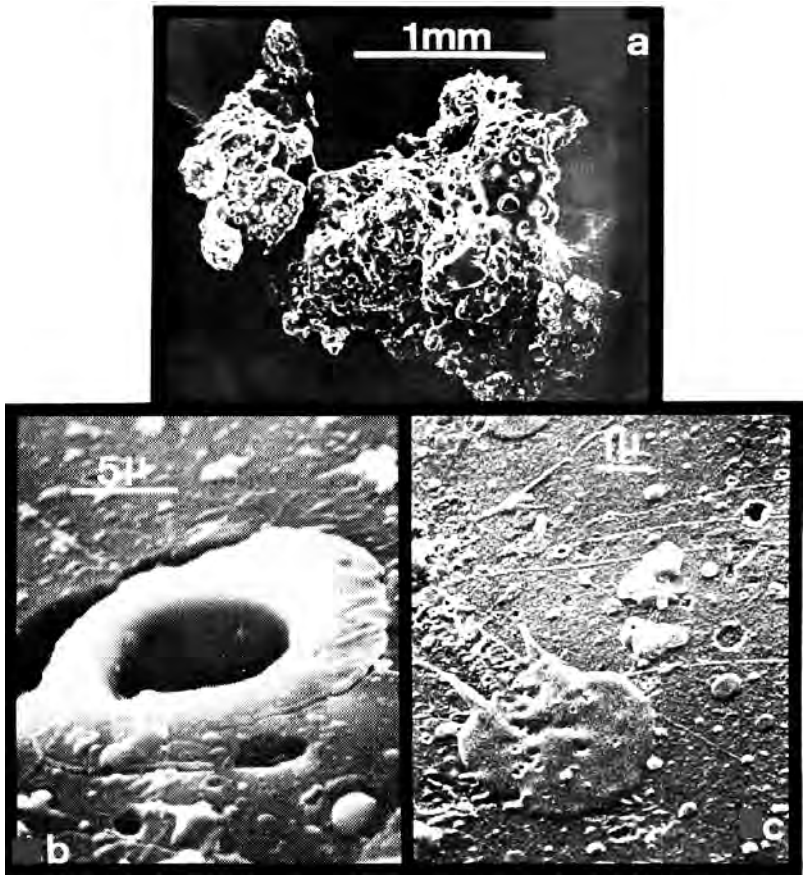

Figure 4. Three examples of small-scale impact processes in the lunar regolith: a millimeter-sized glassy agglutinate (*a*), a microcrater a few micrometers in diameter (*b*) and a glassy splash on a lunar dust grain (*c*).

Craters as a chronometer of the surface of solar system bodies

As small craters have shorter lifetimes, the crater size frequency distribution of a surface presents two domains: the saturation region, at small sizes, where craters are in a steady state, and the production region, characterized by a steeper dependence on size, corresponding to the large craters which have in general survived since their formation. Only the latter is of interest when attempting to use the cratering record for determining the age of a surface. The size distribution in the production region is roughly similar for surfaces throughout the solar system, from Mercury to the satellites of Jupiter (see JUPITER: SATELLITES). This is considered to be a consequence of the scattering of impactors across the solar system by gravitational perturbations, which do not modify the mass distribution of a population.

There is no controversy if one sticks to relative ages: on a given body, a region with few large craters is younger than another region with a higher density of such features. If the age is younger than 4 billion years, in the steady-state domain of secondary impacting bodies, it is expected to be proportional to the density of large craters. Beyond that, the steep increase in flux means that age differences of a few 100 million years may result in very different crater densities. As the overall rate is different for each region of the solar system, the determination of absolute ages from the cratering record is to a large extent model dependent. As an example, the ages derived for old Mars terrains can differ by more than a billion years, and a similar controversy is building up for EUROPA, a satellite of Jupiter. Its highly spherical surface could be resurfaced over short time scales according to the proponents of a global ocean a few 10 km below the surface.

The Moon represents up to now a unique situation: the samples obtained by the APOLLO and LUNA missions provide absolute ages for nine regions, two in highlands and seven in mare, which span more than 1.2 billion years. Thus, lunar samples provide a calibration for cratering ages to within a few 10 million years. The controversies on the age of surfaces for other planets will be resolved as soon as even a few samples are available. A sample return from Mars can be expected within the next 10 years. Even a single absolute age determination will strongly constrain the ages of all surface units on the planet by calibrating the crater production curve. Alternately, one could consider

Figure 5. Copernicus is one of the most spectacular ray craters on the lunar surface and has a diametre of 110 km. As it lies near the center of the nearside, it was one of the first craters to be studied extensively from the ground. Its rays extend over more than 1000 km. A smaller ray crater, Kepler, lies to the west of Copernicus.

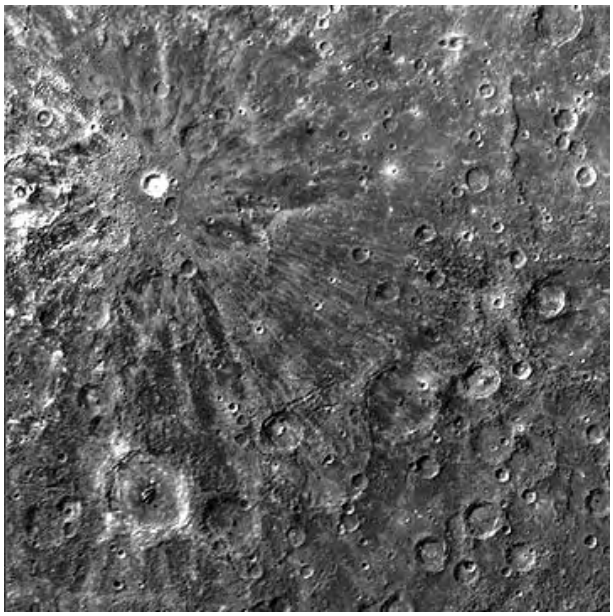

Figure 6. Copley is a 30 km sized ray crater on Mercury. The relatively weak contrast between the rays and the underlying material when compared to Copernicus may be attributed to the efficient maturity processes on the closest planet to the Sun, where impact velocities and particle fluxes are highest.

in situ determinations of radioisotopic ages, but this still represents a formidable challenge

The large-scale effects of impact cratering

Impact cratering is a major process for the evolution of the surfaces of solar system bodies. Its role can be discussed as a function of the age of the surface. Few bodies have retained a high level of internal activity until now. Apart from our Earth, only VENUS and Mars have had significant magmatic episodes during the last two billion years. Tidal heating still drives extensive internal processses for the two innermost Galilean satellites, IO and Europa. Similar processes have occurred on DIONE and ENCELADUS, two satellites of Saturn, as well as MIRANDA, a satellite of Uranus. On Ganymede, phase changes of the ice play a major role, and the surface of cometary nuclei is ablated by the sublimation of volatiles. Erosion can be a major factor for solid planetary bodies with an atmosphere (Earth, Mars, Venus and TITAN). For surfaces younger than a few hundred million years, cratering is a rare, catastrophic event which plays a minor role for the local topography.

At the other end of the scale, the surfaces of asteroids, small icy satellites, CALLISTO and the highlands of Mercury and the Moon are more than 4 billion years old. They have witnessed the high-flux period of the accretionary tail. Their trademark is a saturation with craters of all sizes. These very high fluxes have fractured the crust over several tens of kilometers. This fractured layer is called a megaregolith. For medium size asteroids, the megaregolith can extend to the center, resulting in a rubble pile structure.

The fractures induced by the largest basins extend to the base of the planetary crust. A few hundred million years later, the heat from the decay of long-lived radionuclides triggers magmatic episodes in the mantle. The lava rises to the surface in the fractured regions and floods preferentially the large basins. This process is at the origin of mare on the Moon and Mercury. Recent advances in planetary astronomy (Hubble Space Telescope, adaptive optics) have made possible the identification of such basaltic regions on VESTA. The same cycle has therefore occurred on differentiated asteroids, but on a much shorter time scale, given the much smaller size of these bodies. The heat source is still under debate. On the Earth, plate tectonics has completely erased the traces of early major impacts. Large-scale crustal weakening due to impacts may, however, have played a role in the very early stages of plate tectonics. Mars represents an interesting intermediate case: the southern hemisphere is lunar like, with the two large basins Hellas and Argyre, while the northern hemisphere (with a extension to the south over the Tharsis region) is dominated by tectonic and volcanic processes (see MARS: SURFACE).

During the last 4 billion years, the impact rate was much lower, and the scale of cratering effects correspondingly smaller. Here and there, a few major

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

impacts still formed large craters (Copernicus and Tycho are the largest craters of this type on the Moon). The steady shower of small impacts resulted in the formation of a debris layers a few meters to a few tens of meters in thickness, the REGOLITH. Regoliths are ubiquitous features of the surfaces of atmosphereless bodies throughout the solar system. Remote sensing techniques which probe the uppermost layers do not give direct information on the bedrock, but on the overlying layer of dust and rocky fragments. Fortunately, in such a situation lateral transport can only be triggered by impacts, hence it has a very inefficient random walk behavior. The lateral mixing scale is a few hundred meters on large bodies such as Mercury, the Moon or large icy satellites. It is inversely proportional to the gravity, which explains the relative homogeneity of the surfaces of small asteroids observed by Galileo (Gaspra and Ida) and Near (Mathilde).

The small-scale effects of impact cratering

The remarkable self-similarity of impact cratering extends down to microscopic sizes. A tiny impact on a single rock or grain on a planetary surface creates a microcrater (figure 4(*b*)) which follows the same scaling rules as macroscopic strength craters in the bedrock. Above a diameter in the range of 40% of the size of the rock or grain, fragmentation occurs. As a result, the size of regolith particles slowly decreases from the coarse fresh EJECTA to a very fine dust (typically 50 μm in size). This process should be quite similar on rocky and icy bodies, as ice has a mechanical behavior similar to a rock at the very low temperatures of the outer solar system.

On rocky bodies, two impact related processes tend to increase particle size. Coating by liquid splashes (figure 4(*c*)) or vapor deposits plays a relatively minor role. The liquid fraction from centimeter-scale impacts can weld together grains, forming glassy agglutinates (figure 4(*a*)), or solidify in flight, forming glass spherules. The proportion of glassy particles increases as a function of the time of exposure to space of a sample, which is defined by the local history of meter-sized craters. The study of lunar samples shows that on the Moon, after a few ten million years within the uppermost centimeter, a steady state is reached in the evolution of the size distribution: agglutination exactly compensates fragmentation while the proportion of glassy particles continues to increase, reaching more than 50% in the most exposed lunar soils.

This evolution of a soil sample from the coarse, crystalline fresh EJECTA to a fine-grained, glass-rich soil is called maturity. It also involves exposure to solar wind particles and cosmic rays. Its most dramatic effect is the lowering of the albedo by more than 30%, as glassy particles are darker than the original crystalline grains. The fresh ejecta form bright rays extending radially from the younger large craters (figures 5 and 6). With the increase of maturity, these rays progressively fade into the background. Maturity is a balance between large-scale cratering, which controls the rate at which fresh material is brought onto the surface, and sub-centimeter-sized impacts which control the formation rate of glassy particles. It is difficult to extrapolate the well known lunar situation to other rocky bodies. However, on Mercury the impact velocities are typically twice as large, generating more liquid material, and the regolith should be more mature than on the Moon. The situation on icy bodies is more difficult to assess. One may expect liquid water droplets formed during impacts to play a similar role in welding together ice grains into 'icy agglutinates' and solidifying in flight, forming ice spherules, but the time evolution of icy regoliths is still highly spectulative.

Crescent

The phase of a body in the solar system when some but less than half of its sunlit side is visible. The only objects to show crescent phases to observers on the Earth are those that can pass between the Earth and the Sun: the inferior planets, Mercury and Venus, and the Moon. However, objects outside the Earth's orbit have been imaged in the crescent phase by spacecraft.

See also: phases of the Moon.

Crimean Astrophysical Observatory

The Crimean Astrophysical Observatory (CrAO) is one of the largest scientific centers in the Ukraine and former Soviet Union. CrAO was formed in June 1945 by the Academy of Sciences of the USSR from the Simeiz Department of the Pulkovo Observatory. Since 1991 CrAO has been controlled and financed by the Ministry of Science and Technology of Ukraine.

The main part of the Observatory is located in Nauchny, about 12 km SE of Bakhchisaraj. The main telescopes are: the 2.6 m Shajn telescope, two 1.25 m telescopes; a ground-based gamma telescope (GT–48) with the mirrors covering an area of 54 m^2, the 1.2 m Solar Tower telescope; as well as a few other smaller instruments.

The Department of Radioastronomy, with its 22 m radio telescope (RT–22) for mm and cm radio waves, is located on the seashore, near Simeiz. RT–22 participates in international programs in the global VLBI network for geodynamical and astrophysical investigations.

The Simeiz Station, founded in 1873, participates in the global network of Satellite Laser Ranging Stations for studies of Earth dynamics, and is located on Mount Koshka at an altitude of 346 m.

CrAO possesses equipment for astrophysical observations over a wide spectral range from gamma rays to radio waves of stars and galaxies, as well as the Sun and solar system.

The main subjects of investigation are: solar activity, helioseismology, structure and chemical composition of stellar atmospheres, stellar and solar magnetic fields, variable stars, extragalactic astronomy, planets, asteroids and geodynamics. Currently, next-generation ground-based and space telescopes as well as astrophysical equipment are being designed and manufactured at CrAO.

More than ten devices have been designed and manufactured by CrAO for space observation. In 1983–89 space observations were carried out with the station 'Astron' launched into a high orbit and equipped with a 0.8 m ultraviolet Ritchey–Cretien telescope, designed and manufactured at the CrAO.

There are 350 employees at the CrAO including about 100 scientists, 16 senior and 40 PhDs.

Critical Density

The mean density of a universe which is just capable of expanding forever. In such a universe (an Einstein–de Sitter universe) the rate of expansion is slowed by gravity and approaches ever closer to zero. If the mean density exceeds the critical value, the expansion will cease at a finite time in the future and the universe thereafter will begin to collapse. If the mean density is less than the critical value, the universe will continue to expand at a rate which decreases towards a constant value.

The magnitude of the critical density is given by $3H_0^2/8\pi G$, where H_0 is the present value of the Hubble constant and G the gravitational constant. Depending on the precise value of the Hubble constant, the value of the critical density is in the region of (5–20) $\times 10^{-27}$ kg m^{-3}, with a probable value in the range (6–10) $\times 10^{-27}$ kg m^{-3}. The latter figure is equivalent to an average of about 3–6 hydrogen atoms per cubic meter of space. Many theoreticians believe that the universe should have a density equal to, or indistinguishably close to, the critical value, but the average density deduced from the amount of visible (luminous) matter is only of the order of 1% of the critical density. Observations of the rotation rates of galaxies and the dynamics of galaxy clusters indicate that there is at least ten times as much dark matter as luminous matter in the universe, but there are growing doubts as to whether there is enough dark matter to give a mean density as high as, or higher than, the critical value.

The ratio of the actual mean density to the critical density (the density parameter) is denoted by the symbol Ω (omega). $\Omega > 1$ if the actual density exceeds the critical value, $\Omega = 1$ if the actual density is equal to the critical density and $\Omega < 1$ if the actual density is less than the critical value.

Crust

The thin outer layer of a differentiated planetary body. Crusts consist of rock and/or ice—rock predominating in the inner solar system, ice in the outer—and have a different composition from the underlying mantle. *Primary crust* is the surface layer formed when the planet first differentiates. It preserves the cratering record from the early bombardment in the solar system's history. Primary crust is found for example in the highlands of Mercury and the Moon, and many of the satellites in the outer solar system. *Secondary crust* is formed when the mantle melts and volcanism leads to the first phase of resurfacing; the floodplains of the lunar maria are secondary crust, as is the whole surface of Venus. *Tertiary crust* is produced on geologically active worlds by the recycling of primary and secondary crust material. On the Earth and Io, continuing volcanism produces tertiary crust; on the Earth plate tectonics is continually recycling the crust, which is also modified by processes such as sedimentation and erosion.

Neutron stars are believed to have a crust consisting predominantly of iron.

Crux

(the (Southern) Cross; abbrev. Cru, gen. Crucis; area 68 sq. deg.) A southern constellation which lies to the north of Musca and is surrounded on three sides by Centaurus. It culminates at midnight in late March. The brightest stars of Crux were included by the ancient Greeks in Centaurus and were cataloged as such by Ptolemy (*c*. AD 100–175) in the *Almagest*, but European navigators separated them out in the sixteenth century and they were included as a constellation in their own right on a celestial globe by the Dutch theologian and geographer Petrus Plancius in 1598.

Crux is the smallest but also one of the most conspicuous of the 88 constellations and (together with Orion and the asterism of the Plough in Ursa Major) one of the best known. Its brightest star, α Crucis (Acrux) is a triple system consisting of two bluish-white (B0.5 and B1) components, magnitudes 1.3 and 1.6, separation 4.1″, and a third, unseen component which revolves around the former in 75.8 days. Other bright stars include β Crucis (Becrux or Mimosa), magnitude 1.3, γ Crucis (Gacrux), magnitude 1.6, and δ Crucis, magnitude 2.8. A line from γ through α (along the longer axis of the cross) points roughly towards the south celestial pole, while a line from δ through β (along the shorter axis) points roughly towards β Centauri. There is one other star brighter than fourth magnitude, ε Crucis, magnitude 3.6, which lies between and slightly offset from the line joining γ and α, and rather spoils the symmetry of the cross—which, if anything, more closely resembles a kite.

Interesting objects in Crux include μ Crucis, a wide binary star system with bluish-white (B2 and B5) components, magnitudes 4.0 and 5.1, separation, 35″, the Jewel Box (NGC 4755), a magnificent open star cluster centered on κ Crucis, and the Coalsack, an area of dark nebulosity silhouetted against the Milky Way which runs through the constellation.

Cubewano

Any of the main stream of Kuiper Belt objects, at 41–47 AU mean distance from the Sun, inclination of orbit ranging up to 30°, eccentricity up to 0.1. Named after the designation, 1992 QB1, of the first Kuiper Belt object, which was discovered by Dave Jewitt (University of Hawaii).

Culmination

The passage of a celestial body across an observer's meridian (also known as 'transit'). Upper culmination (upper transit) is the passage of the body through the point at which its altitude above the horizon is greatest (and zenith distance is least). For example, the Sun reaches upper culmination at noon. Lower culmination (lower transit) is the crossing further from the zenith. If the body is circumpolar, the point of lower culmination will be above the horizon; otherwise, lower culmination occurs when the body is at its maximum angular distance below the observer's horizon.

Curtis, Heber Doust (1872–1942)

Astronomer, born in Muskegon, MI, became director of the Allegheny Observatory of the University of Pittsburgh and professor of astronomy and director of the Astronomical Observatories of the University of Michigan. Surveyed nebulae with the Lick Observatory Crossley reflecting telescope, identified that some long thin-looking nebulae were identical with the spiral nebulae, but seen edge on with a band of obscuring matter like that seen centrally in the Milky Way. Interpreted the Zone of Avoidance, in which few or no spiral nebulae were seen near the Milky Way, as being due to the obscuration by the Milky Way's obscuring matter, and concluded that spiral nebulae were Milky Way galaxies outside our Galaxy. Engaged in the 'great debate' with HARLOW SHAPLEY in Washington 1920, arguing correctly against Shapley's view that spiral nebulae were minor objects within an immensely bigger Milky Way structure.

Cusp Cap

A brightening at one or other of the tips—*cusps*—of the crescent phase of Venus, as seen from Earth. Cusp caps were first reported by the German amateur astronomer Baron Franz Paula von Gruithuisen in 1813, and have been recorded by telescopic observers ever since. They were named by analogy with the Earth's polar caps; early observers fancied they were seeing glimpses of a possibly Earth-like surface through breaks in the Venusian cloud cover. Cusp caps take the form of bright patches at the horns of the crescent. On the side of a cusp cap away from the cusp itself there is often a darker band known as a *cusp collar*. Both caps and collars show short- and long-term variations in brightness and size.

It was once thought that the cusp caps were contrast effects, but images from the Mariner 10 and Pioneer Venus spacecraft showed that the brightenings, along with other 'deformities' in the planet's limb and terminator as observed from Earth, are real. They are related to the planet's atmospheric circulation. On Venus the predominant pattern is a single Hadley cell in each hemisphere which circulates from the equator almost to the poles. The cusp collars are thought to represent the northern- and southernmost limits of the circulation pattern, and the variations in the caps and collars are thought to reflect short- and long-term variations in the Hadley-cell circulation.

Cygnus

(the Swan; abbrev. Cyg, gen. Cygni; area 804 sq. deg.) A northern constellation which lies between Cepheus and Vulpecula, and culminates at midnight in late July. Its origin is uncertain, though it was known to the ancient Greeks, who identified it with one of the forms assumed by Zeus during his amorous pursuits, or with other mythological swans. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large, conspicuous constellation, Cygnus is easily recognized by the cruciform configuration of its five brightest stars, which gives it its alternative name of the Northern Cross. Its brightest star, α Cygni (Deneb or Arided), magnitude 1.3, marks the tail of the swan and is one of the stars that, together with α Lyrae (Vega) and α Aquilae (Altair), makes up the asterism of the Summer Triangle. Other bright stars include γ Cygni (Sadr), magnitude 2.2, ε Cygni (Gienah), magnitude 2.5, δ Cygni, a close binary with bluish-white (B9.5) and white (F1) components, magnitudes 2.9 and 6.6, separation 2.5″, period about 800 years, and β Cygni (Albireo), in the head of the swan, a particularly fine visual binary with orange and bluish-white (K3 and B8) components, magnitudes, 3.1 and 5.1, separation 34″, the former of which is itself a very close binary. There are ten other stars of magnitude 4.0 or brighter.

Other interesting double stars include o^1 Cygni, a triple system consisting of orange (K2) and bluish-white (A5) components, magnitudes 3.8 and 4.8, separation 338″, and a third, bluish-white (B5) component, magnitude 7.0, separation 107″ from the latter, and 61 Cygni, a binary with orange (K5 and K7) components, magnitudes 5.2 and 6.1, separation 30″, period about 650 years, the primary of which was the first star to have its trigonometrical parallax measured, in 1838. Interesting variable stars in Cygnus include the Mira-type variable χ Cygni (range 3.3–14.2, period about 409 days), the eruptive variable P Cygni (range 3–6, last outburst 1655) and the brightest U Germinorum star, SS Cygni (range 7.7–12.4, mean period 49.5 days), which is also an x-ray binary.

Cygnus lies in a particularly rich part of the northern Milky Way, which is at its brightest between γ and β, and is divided to the east by the Great Rift (or Cygnus Rift), a band of dark, absorption nebulae that continues through Aquila and Serpens Cauda to Ophiuchus, where it broadens out. Among the many open star clusters and nebulae in Cygnus are M39 (NGC 7092), a fifth-magnitude open cluster which contains a couple of dozen stars between seventh and tenth magnitude, the Veil Nebula (NGC 6960, 6974, 6979 and 6992–5), which is the optical component of the Cygnus Loop, the remnant of a supernova that exploded about 30 000 years ago, and NGC 7000 (the North America Nebula), a large (2°) area of mixed nebulosity.

Also in Cygnus are Cygnus X-1, an x-ray binary whose smaller component may be a black hole, and Cygnus A, a powerful extragalactic radio source thought to be two galaxies in collision.

Cygnus A

The brightest radio source in the constellation of Cygnus, and the second-brightest cosmic radio source in the sky. This radio source, which had been detected in 1944 by Grote Reber (1911–), was shown in 1951 to coincide in position with a remote galaxy of unusual appearance (the galaxy appeared double, but is now known to be a single galaxy crossed by a lane of dust). Cygnus A was the first radio source to be detected beyond the confines of our own galaxy and the first example of what is now called a radio galaxy.

Cygnus A, which lies at a distance of about 750 million light-years, has a radio output a million times more powerful than that of a conventional galaxy like the Milky Way. At radio frequencies, it has a classic double-lobed structure, the main body of radio emission emanating from two elongated clouds that extend to a distance of some 200 000 light-years on either side of the center of the galaxy. The central radio source is linked to the outer lobes by two long, narrow filaments that are composed of energetic radio-emitting electrons that have been ejected from the core of the galaxy. The galaxy itself, which is exceptionally massive (about 10^{14} solar masses), is also an x-ray source, the x-ray emission coming from a distribution of hot gas with a temperature in the region of 10^8 K.

The intensity, or flux density, of Cygnus A at a wavelength of 20 cm in the radio region is about 1495 janskys.

Cygnus Loop

A large supernova remnant in the constellation Cygnus, measuring nearly 3° across. Some arcs of the Loop, known collectively as the Veil Nebula (or sometimes the Cirrus Nebula), are visible at optical wavelengths; radio, infrared and x-ray images reveal the complete Loop. The brightest part of the Veil is NGC 6992–5, to the east (centered on position RA $20^{h}\ 56.4^{m}$, dec. +31° 43′); the western section is NGC 6960 (RA $20^{h}\ 45.7^{m}$, dec. +30° 43′). Other sections are NGC 6974 (RA $20^{h}\ 50.8^{m}$, dec. +31° 52′) and NGC 6979 (RA $20^{h}\ 51.0^{m}$, dec. +32° 09′).

Cygnus X-1

Cygnus X-1 is one of the strongest x-ray sources. It is the first celestial object for which we had reasonably convincing evidence that it is a BLACK HOLE. Its x-ray properties include an ultra-soft spectrum, compared to massive x-ray binaries containing a neutron star, rapid ($\sim$ 1 s) flickering, and high/low flux states with different spectral characteristics. In 1971, a RADIO SOURCE appeared at the time of a transition between the two flux states. This source is coincident with the O9.7Iab supergiant HDE226868. This star was found to be a single-line spectroscopic binary and ellipsoidal variable with an orbital period of 5.6 days.

Subsequent x-ray observations showed that the x-ray flux varies with the orbital period and another period found in the light curve, thereby confirming that Cygnus X-1 is a massive X-RAY BINARY. The radial velocities of H and He II emission lines in the optical spectra show that mass is flowing from HDE226868 toward Cygnus X-1. The emission line profiles suggest that mass is being transferred by a focused stellar wind.

Since Cygnus X-1 is not an eclipsing binary, we cannot determine the mass of the x-ray source with precision. However, we can place strong limits on critical system parameters by using a light curve synthesis program to model the ellipsoidal light variations and absorption line widths of HDE22686. The models are further constrained by the effective temperature of the star, the absorption line radial velocity curve, and the distance estimated from the increase in various effects of the interstellar medium with distance determined by measuring stars in the field around HDE226868. Fortunately, results from the modelling are not sensitive to assumptions that must be made during the process.

This analysis yields a strong lower limit on the mass of Cygnus X-1, $M_{\rm x} > 7M_{\odot}$. This is more than twice the upper limit for the mass of a neutron star, $M_{\rm ns} < 3.2M_{\odot}$, according to the theory of GENERAL RELATIVITY. Cygnus X-1 was the first object for which there was a convincing argument that it is a black hole. It was nearly a decade after the first recognition that Cygnus X-1 must be a black hole before another example was discovered.

The x-ray source

The strong x-ray source Cygnus X-1 was first discovered by a rocket-borne x-ray detector in 1964. It is one of the five strongest x-ray sources in the energy range 2–10 keV. It has two distinct x-ray 'states', originally labeled *high* and *low*. The x-ray spectrum is harder, that is, has a greater proportion of high-energy photons, in the low state, not only because of a decline in the low-energy x-ray flux, but also because the x-ray flux for energies greater than 10 keV increases at the same time. Similarly, the high-energy flux declines when the low-energy flux rises. As a result, it is now common practice to label the 'states' *soft* and *hard* respectively. Long-term monitoring of Cygnus X-1 has shown that the different states can last for weeks to years. There are no characteristic time scales for the two states. Moreover, at least two other 'states' have been observed at least once. These states must reflect changes in the accretion rate or structure of the ACCRETION DISK, but as yet no one has offered a model that explains all of the observations.

The x-ray flux variations are not confined to the state changes. In fact, the x-ray flux varies on time scales from $\sim$1 ms to at least the time scales associated with the state changes. These include flux variations that are modulated with the orbital period and a variable, longer period that may be a precession period of some structure in the system. These are superimposed on a background of shot noise and occasional flares.

The 5.6 day x-ray flux variation is easiest to understand. The minima last for 27% of the orbital period and are centered precisely around the time of superior conjunction of the black hole with the O-star. The minima are deeper in the lower energy bands. The phasing and spectral shape of the minima indicate that the variation is due to photoelectric absorption by the focused stellar wind from the O-star. These variations are observed only during the hard state. The anticorrelation of the Hα emission line equivalent width with the soft x-ray flux during the 1996 soft state lends support to this idea.

Monitoring of the 3–12 keV flux of Cygnus X-1 from 1969 to 1980 showed that the average flux varies with a period $P = 294 \pm 4$ days. The x-ray flux is at the maximum level for approximately 40% of the 294 day period. The decline to minimum flux, which is about 75% of maximum flux, takes half as long as the recovery back to maximum flux. From August 1996 to September 1998, during the hard state following the 1996 soft state, both the 2–10 keV and 20–100 keV flux varied with a period of 142 ± 7 days. The amplitude in the 2–10 keV band was nearly double that observed earlier and the shape of the flux curve was almost a mirror image of the the one for the 294 day period. It remains to be seen whether the curious relationship between the periods and light curves is anything more than a remarkable coincidence.

The short-time-scale variations of the x-ray flux can be described by shot noise, a type of noise resulting from the superposition of a large number of disturbances (shots) that occur at random. The shots have a characteristic time scale of about 20 ms, but their characteristics vary in a complex fashion with energy and x-ray state. The shots all rise more slowly to peak intensity than they decline. The peaks of the shots in the higher energies are narrower and more asymmetric than those in the low energy bands. During the hard and transition states, the average hardness of the shots is lower than the steady emission. During the soft state, the average hardness of the shots is greater than the steady emission. The hard x-ray shots lag behind the soft x-ray shots by an amount that is a function of energy. This delay is smallest for the hard state, and slightly larger than the soft state, and much larger for the transition state. A separate study of the Fourier time lag, the time lag between the same phase in two different

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

time series, reached similar conclusions using x-ray hard state data. This implies that nearly all of the hard and soft flux variations occur simultaneously. At the same time, the time series in different energy channels show nearly complete coherence down to ≈0.02 Hz, and after a slight loss of coherence near 10^{-2} Hz, recovered back to nearly unity at 0.005 Hz. This is difficult to understand if the hard and soft flux variations are produced nearly simultaneously, since the hard photons are scattered many more times than the soft photons.

The hard state spectrum of Cygnus X-1 can be represented by the sum of a soft thermal component and a hard, non-thermal power-law component with a high-energy cut-off near 150 keV. The power-law spectrum is modified by reprocessing features, in particular a weak iron fluoresence line at 6.4 keV and possibly a Compton reflection hump near 30 keV. During a soft state, the soft thermal component increases by a factor of several while the hard non-thermal power-law component declines by 10–20%. All four spectral components are usually explained in the context of accretion disk corona models in which the thermal radiation originates in an accretion disk and is Comptonized in a hot plasma, the 'accretion disk corona'. These models can successfully reproduce the spectral variations between the soft and hard states if the accretion disk extends inwards to the last stable orbit around the black hole and the central corona fills a small volume during the soft state, and the inner edge of the disk is much further from the black hole and the central corona much larger in the hard state. However, there is no generally accepted model for the geometry or dynamics of the accretion disk/accretion disk corona system. At this time, it is not clear that any of the models have succeeded in reproducing anything more than the x-ray spectrum. Attempts to explain the short-time-scale variability have had limited success, at best, and the precession has been treated qualitatively as a separate problem.

The optical light curves

In order to determine the masses of stars in a BINARY SYSTEM we need to determine its orbital inclination i, where i is the angle between the orbit plane and the plane of the sky. In principle, when there are no eclipses, and a binary system cannot be resolved, optical polarimetry is the best method to determine i. However, HDE226868 is so faint that the photometric errors render the polarimetric result, $25^\circ < i < 65^\circ$, essentially useless for determining i.

Because of the nature of the mass transfer in the Cygnus X-1 system, we expect that HDE226868 comes very close to filling its ROCHE LOBE. This means that the star will be strongly distorted into a roughly ellipsoidal shape with the long axis of the ellipsoid aligned with the line between the star and the black hole and the end of the ellipsoid directed toward the black hole drawn out into a point. Regions of the star that are farther from the center will have lower surface brightnesses than those that are close to the center. This is called gravity darkening or gravity brightening.

If there are no other light sources and we view the tidally distorted star from the direction of the orbit plane, i.e. $i = 90^\circ$, the light curve will have a shallower, rounded minimum at orbital phase $\phi = 0.0$, superior conjuction of the black hole, a sharper, deeper minimum at $\phi = 0.5$, inferior conjunction of the black hole, and broad equal maximum between the minimum. The luminous flux is smaller at the conjunctions because the areas of the star projected on the sky are smaller, the surface brightnesses of those regions are lower because of the effects of gravity darkening. The depths of the minima depend on temperature. In this case, the depths will increase with decreasing wavelength because of the high effective temperature of HDE226868.

In the more general case, the amplitude of the light variation depends on the mass ratio $q = M_x/M_{opt}$, where M_x is the mass of the black hole, and M_{opt} is the mass of HDE226868, the fill-out factor ρ, the ratio of the volume radius of the star (i.e. the radius of a sphere with volume equivalent to that of the star) to the radius of a sphere with a volume equivalent to the volume of the Roche lobe, and orbital inclination angle i. Larger q and ρ will increase the tidal distortion of the star and thereby increase the amplitude of the light curve. As i is decreased from 90°, the amplitude of the light curve is reduced and the differences in amplitude and shape between the two minima gradually disappear. In addition, at low inclinations, the gravity darkening effects become so small that the amplitude of the light curves are independent of wavelength in the optical region at least.

The optical light curves of HDE226868 observed during the hard state of the x-ray source look approximately like those expected for a low-inclination system. The amplitudes of the U, B and V light curves are approximately 0.025 mag. The light curve is phased as expected with respect to the radial velocity curve. If HDE226868 fills its Roche lobe, the semi-amplitude of the light curve is almost independent of the mass ratio, and it can be used to place a lower limit on the orbital inclination angle $i \geq 27^\circ$.

There are two problems that make it difficult to work with the light curves. First, the rms scatter about the light curve is 0.022 mag, almost half the amplitude of the intrinsic variability. This is comparable to the variability seen in photometry of single, luminous OB stars and is probably due to the same cause—either density inhomogeneities in their winds or multiperiodic non-radial pulsation. Unfortunately, this extra intrinsic variability means that we have to average observations over several years get reliable ellipsoidal light curves. Second, an additional component of scatter in the ellipsoidal light curves is due to periodic changes in the shape of the light curve.

After the 5.6 day ellipsoidal light curves have been subtracted from the luminous fluxes in the U and B bands obtained in the during the x-ray hard state between 1972 and 1983, they have light curves with $P = 294$ and the same shape and phasing as the x-ray flux in data taken between 1972 and 1983. The variation is largest,

Dirac House, Temple Back, Bristol, BS1 6BE, UK

0.0061 ± 0.0012 mag, in U, smaller in B, and statistically undetectable in the V band. Comparison of the 5.6 day light curves obtained during the x-ray bright and faint phases of the 294 day period show that when the x-ray source is brighter, the optical light curves are brighter at all phases except around the time of inferior conjunction of the x-ray source. The phasing and relative amplitude of the optical light curves suggests that the optical variations are due to a hot source between the x-ray source and HDE226868. No models have been proposed that explain why the optical and x-ray fluxes vary in phase. The orbital modulation of the optical light curves disappeared during the 1996 soft x-ray state, while the 142 day long-term modulation continued. The orbital modulation returned to normal when the x-ray source returned to the hard state.

Clearly these results raise serious questions about the standard assumptions that are made in various schemes to derive the mass of the black hole in Cygnus X-1. A careful inspection of the many mean light curves is not encouraging. None of them is a good fit to a standard ellipsoidal light curve model.

HDE226868: spectroscopic observations

The optical spectrum of HDE226868 has been classified O9.7Iab(p-var), where the peculiarity relates to weak, variable emission in the He II λ468.6 nm line. Weak variable emission is also present in the Hα, Hβ and Hγ lines. The absorption line spectrum is very similar to those of comparable supergiants, but the star's atmosphere may be overabundant in He and C. RADIAL VELOCITIES measured from the absorption lines show that HDE226868 is a single-line spectroscopic binary with a orbital period $P = 5.5998$ days and radial velocity semiamplitude $K_{\rm opt} = 74.7$ km s^{-1}. This yields a mass function

$$f(M) = \frac{M_{\rm x} \sin^3 i}{(M_{\rm opt} + M_{\rm x})^2} = 0.25 \pm 0.01.$$

Measures of the radial velocities of the emission lines yield a velocity curve where the maximum velocity is shifted about $0.75P$ from maximum radial velocity of the absorption lines. This indicates that the emission lines are formed in gas that is lying on or near the line joining the two stars and is flowing from the visible star to the x-ray source. This shows that the visible star must fill, or nearly fill, its Roche lobe. Detailed analyses of the emission profiles show that they are blends of two components, a P Cygni profile[1] that follows the absorption line radial velocity curve and a broad, roughly symmetric, emission feature that is shifted $0.86P$ with respect to the absorption line velocity curve.

These analyses indicate that the emission lines form in a region less than $0.1R_{\rm opt}$ above the surface of HDE226868, where $R_{\rm opt}$ is the star's radius. The average flow velocity in this region is less than 100 km s^{-1}. The width of the emission features, FWHM < 400 km s^{-1} is consistent with the velocity gradient expected in a focused stellar wind. The flow velocity and velocity gradient in a gas stream are unlikely to be as large so close to the star.

The emission from the outflow is not occulted. If the star fills 90% of its Roche lobe and we make a reasonable allowance for error in the position where the emission forms, this implies that $i < 55^\circ$. The limit is reduced significantly if the star fills a larger fraction of its Roche lobe.

The upper limit on the peak intensity of Hα emission from the accretion disk is 3% of the continuum flux from HDE226868. This is not surprising because the accretion disk is expected to be much fainter than HDE226868.

The mass of the compact object

The light and velocity curves of HDE22686 do not provide the information required to solve for the critical parameters of the binary system, especially the mass of the x-ray source. It is possible, however, to obtain significant limits on the important parameters by combining information derived from these curves with other data. If the spin and orbital angular momentum vectors are aligned, the ratio of the projected rotation velocity $V \sin i$ to the absorption-line velocity curve semi-amplitude $K_{\rm opt}$ is independent of the orbital inclination angle

$$\frac{V \sin i}{K_{\rm opt}} = \rho\Omega \left(\frac{1}{q} + 1\right) \Phi(\Omega, q)$$

where Ω is the ratio of the star's spin angular velocity to its orbital angular velocity, q is the mass ratio, and $\Phi(\Omega, q)$ is the Roche lobe volume radius divided by the system separation. This relation can be used to derive q for a grid of ρ and Ω.

Theoretical calculations show that there will be catastrophic Roche lobe overflow that would smother the x-ray source if $\rho = 1$. Moreover, theoretical calculations of emission line profiles for focused wind models show that for $\rho < 0.9$ the wind density is not high enough along the line joining the stars to produce the observed emission. The circularity of the orbit suggests that tidal forces will have had enough time to bring the star into near synchronous orbit, so it is reasonable to confine our grid to values of Ω near unity.

The amplitude of the light curve depends on q, ρ, Ω and i. The shape of the star is modeled with a potential that includes the effects of radiation pressure from both the star and x-ray source and asynchronous rotation, to first order. The modeling process is begun by guessing values of q and i, and these are used to obtain the component masses, the radius and surface gravity of the visible star. The V magnitude and extinction can be used to relate the visible star's radius to its distance d in kpc, $R_{\rm opt} = (9.7 \pm 0.9)d$. The distance can then be used to compute the luminosities of the visible star and x-ray source, which are required to estimate the ratio of

[1] A P Cygni profile consists of a blue shifted-absorption trough and a red-shifted emission line that joined at approximately the wavelength of the line in the reference frame of the star. They form in spherically symmetric outflows from a star.

the radiative to gravitational acceleration that are required when including the effects of radiation in calculating the potentials. The fluxes and specific intensity profiles are calculated using a model atmosphere code. The specific intensity profiles are calculated for $T_{\rm eff} = 27\,500$ K and surface gravity that is appropriate for the parameters selected.

These data are input into a light curve synthesis code, where they are integrated over the surface of the star while taking into account the effects of gravity darkening and limb darkening. If the FWHM of the flux line profile and the amplitude of the light curve do not match the observations, q and i are adjusted, and the process is repeated until a match is obtained. Since the amplitude of the light curve is most sensitive to i, and the FWHM depends entirely on q, the selection of adjustment is relatively easy and the process converges within a few iterations. The 1972 to 1983 V light curve was used for this purpose because it was the one that seemed least affected by the perturbations noted earlier.

Fortunately, the results of this exercise are insensitive to the assumptions made during the calculations. These include the value of the macroturbulent velocity used in calculating the theoretical line profiles, the inclusion or omission of the effects of radiation pressure, and coalignment of the angular momentum vectors. For near synchronous rotation and a generous allowance for the uncertainties, $M_{\rm opt} = 33 \pm 9\ M_\odot$ and $M_{\rm x} = 16 \pm 5\ M_\odot$. These values are consistent with distance estimates based on the UV and optical colors of HDE226868 and studies of the interstellar absorption as a function of distance for stars in the surrounding field. The absolute lower limit on the distance based on these data is $d > 1.7$ kpc. This corresponds to $M_{\rm opt} = 20\ M_\odot$ and $M_{\rm x} = 7\ M_\odot$. An alternate analysis based on unified atmosphere-wind models fitted to the spectra of HDE226868 obtained somewhat lower values, $M_{\rm opt} = 18\ M_\odot$ and $M_{\rm x} = 10 M_\odot$. This result also depends implicitly on the light curves to obtain the inclination, though less so than the first method, and no error estimates were given. If they had been, it is likely that the errors for the two methods would have overlapped.

Dante, Egnatio [Egnazio, Ignazio] (1536–86)

Astronomer, instrument-maker and cartographer. Born in Perugio, Italy, of a father who also apparently made astronomical instruments, he became a Dominican monk, and published works on Sacrobosco's *Sphere*, and other astronomical and mathematical topics. He made maps under the patronage of Cosimo I de' Medici, and a large terrestrial globe, which still exists. He was later professor of mathematics at Pisa and Bologna. In 1574 he determined by observation that the equinox was 11 days earlier than the calendar then in use. Dante continued to refine the observations to quantify this accumulated error, and, being appointed cosmographer and mathematician to Gregory XIII he was commissioned to map the papal states and to lead work to reform the calendar.

Dark Matter in Galaxies

Dark matter in spiral galaxies

SPIRAL GALAXIES are flat rotating systems. The stars and gas in the disk are moving in nearly circular orbits, with the gravitational field of the galaxy providing the inward acceleration required for the circular motion. The rotation of these galaxies is usually not like a solid body: the angular velocity of the rotation typically decreases with radius. To a fair approximation, assuming Newtonian gravity, the rotational velocity $V(r)$ at radius r is related to the total mass $M(r)$ within radius r by the equation $V^2(r) = GM(r)/r$, where G is the gravitational constant.

The radial variation of the rotational velocity (the rotation curve) is most readily measured from the gas in the disks. The emission lines of ionized gas in the inner regions are measured with optical spectrographs. With radio synthesis telescopes, rotation curves can be measured from the neutral hydrogen (H I) which emits a narrow spectral line at 1420 MHz (21 cm wavelength). The interest in measuring rotation curves of spiral galaxies is that they give a direct measure of the radial distribution of the total gravitating mass.

Until the early 1970s, most of the rotation data for spirals came from optical observations which did not extend beyond the luminous inner regions. At that time, the optical rotation curves seemed consistent with the distribution of luminous matter. With the construction of RADIO TELESCOPES like the Westerbork Radio Synthesis Telescope in The Netherlands, it became possible to measure the distribution and rotation of the H I in spiral galaxies. It was soon discovered that the H I in many spirals extended far beyond the starlight, and that the H I rotation curves in such galaxies often showed nearly constant rotational velocity out to the radial limits of the data.

This was unexpected, because a flat rotation curve means that the total mass of the spiral within some radius r increases linearly with r, while the total luminosity approaches a finite asymptotic limit as r increases. It soon became clear that a large amount of invisible gravitating mass (more than 90% of the total mass in some examples) is needed to explain these flat rotation curves.

The problem is illustrated in figure 1. The rotation curve comes from H I observations of a well studied spiral, NGC 3198. The curve labelled *disk* is the rotation curve that would be expected if the surface mass density in this galaxy were proportional to the light distribution shown in the upper panel. In this analysis, the constant of proportionality (the ratio of mass to light) was made as large as possible, with the criterion that the total expected rotation curve should not exceed the observed rotation curve. The gas in the galaxy also contributes to the expected rotation curve, as shown by the curve labelled *gas* (see also GAS IN GALAXIES). The contributions to the expected rotation curve from stars and gas must be added in quadrature to derive the total expected rotation curve. From the curves in this figure, there is no way that the stars and gas together can produce the flat observed rotation curve. An additional massive and extended distribution of dark matter is needed. The rotation contribution for a simple dark halo model is shown in the figure: the model is chosen so that the dark halo plus disk plus gas together give the rotation curve that passes through most of the observed points in the figure. At the radial limit of the data, the dark halo is providing most of the total gravitational field.

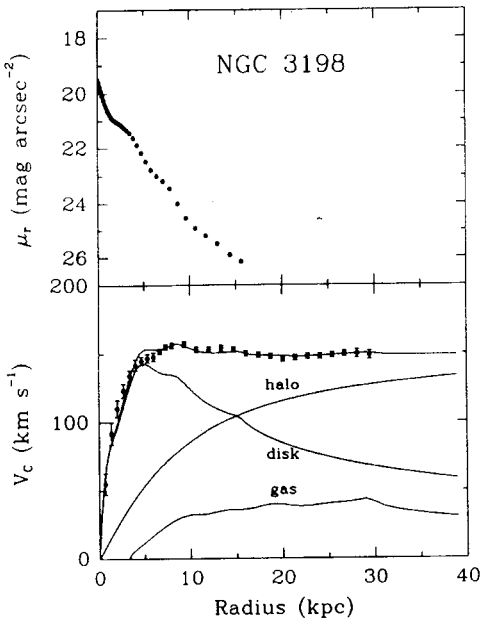

Figure 1. The upper panel shows the R-band radial surface brightness distribution of the spiral galaxy NGC 3198. The lower panel shows its H I rotation curve (points). The curve labelled *disk* shows the expected rotation curve if the surface density distribution followed the surface brightness distribution in the upper panel. The curve labelled *gas* is the contribution to the rotation curve from the observed gas. Together, the gas and the disk cannot reproduce the observed flat rotation curve at large radius. An extra gravitating component, the dark halo, is needed. The curve labelled *halo* is the rotation curve of the adopted dark halo model: the three labelled rotation curves, when added in quadrature, produce the total rotation curve that passes through the observed points. (From Begeman K 1987 *PhD Thesis* University of Groningen.)

The halo model in figure 1 is a minimum halo, in the sense that the contribution of the disk to the rotation curve was made as large as possible. If a lower mass-to-light (M/L) ratio had been adopted for the disk, then a more centrally concentrated halo would be needed to make up the larger discrepancy between the observed and expected rotation curves. It is difficult to measure the M/L ratio for disks independently of the rotation curve itself, and there is still a lot of controversy about the correctness of the maximum disk approach as shown in figure 1.

The situation shown in figure 1 is typical of almost

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

all DISK GALAXIES that have extended H I distributions, including the small DWARF IRREGULAR GALAXIES that are also in rotational equilibrium. In almost every example, a massive dark halo that dominates the enclosed mass $M(r)$ at large r is needed to explain the observed rotation curves. The nature of this dark matter remains unknown (see DARK MATTER: ITS NATURE), and is one of the great problems of modern astrophysics.

For decompositions as shown in the figure, the dark halo is often modelled for simplicity as a spherical system with a radial volume density distribution of the form $\rho(r) = \rho(0)/(1 + r^2/a^2)$, where a is a scale length and $\rho(0)$ the central density. This particular distribution is chosen because it generates a flat rotation curve at large radius.

The spherical shape is simply an assumption. It turns out to be very difficult to measure the shapes of dark halos. The thin neutral hydrogen layer in edge-on spirals is observed to flare beyond the edge of the stellar disk, where the vertical restoring force of the disk is reduced. The extent of this flaring can be used to estimate the flattening of the dark halo (a flat halo would lead to less flaring). Another idea is to study the POLAR RING GALAXIES, in which material is rotating in two orthogonal planes so the gravitational field in both planes can be measured. Both of these approaches have uncertainties, but they hint that dark halos may be significantly flattened.

In figure 1, the gently rising rotation curves for the halo and for the gas are roughly similar in shape out to the radial limit of the observations. This is again typical for disk galaxies with extended H I distributions, and hints that the gas and the dark matter distributions are in some way closely related. Some authors have argued that the dark matter may be in the form of cold gas, but this remains contentious.

Dark matter in our Galaxy

Although our location in the disk of our Galaxy makes it difficult to measure its rotation curve out to large radius, other less secure mass estimators become possible in this situation. For example, the velocities of halo stars out to distances of 100 kpc from the Sun can be used to estimate the total galactic mass. Some halo stars pass through the solar neighborhood at velocities in excess of 600 km s^{-1}. If these stars are bound to the Galaxy, then they provide another mass estimator. The ANDROMEDA GALAXY, at a distance of 770 kpc, is approaching the Milky Way at about 120 km s^{-1}, which provides yet another mass estimator by assuming that the combined mass of the two galaxies is sufficient to turn around their initial expansion within the lifetime of the universe. All of these estimators together indicate that the enclosed mass of the Milky Way increases linearly with radius out to at least 150 kpc and that its total mass is about $15 \times 10^{11} M_\odot$. The luminous mass is unlikely to exceed $1.2 \times 10^{11} M_\odot$, so the mass of our Galaxy is probably more than 90% dark.

If the dark matter is in the form of compact objects of stellar or substellar mass (e.g. jupiters, white or brown dwarfs, neutron stars), then dark halo objects passing between the observer and a distant star cause the distant star to brighten as they pass, through GRAVITATIONAL LENSING. The duration of the brightening depends on the mass and velocity of the lens and the geometry of the event. For stars in the MAGELLANIC CLOUDS, the typical duration of the brightening would be a few months for dark halo objects of solar mass. Several groups have attempted to detect dark objects in this way. The MACHO experiment monitored the brightnesses of several million stars in the LMC over a period of about 7 years, and has detected about 15 lensing events. If these lensing objects lie in the galactic halo, then they provide about half of the total dark matter and their individual masses are about $0.5 M_\odot$. This mass is typical of white dwarfs and suggests that these dark objects could be old WHITE DWARFS, perhaps remnants of a very early and very massive burst of star formation. There is no evidence for a significant population of luminous stars associated with the dark halo, so a rather special stellar mass function would be needed to produce large numbers of old white dwarfs without producing even larger numbers of old luminous stars. It remains possible that the lenses are not in the galactic halo. For example, if the LMC is sufficiently extended along the line of sight, the lenses could be objects in the LMC lensing other objects in the LMC.

Dark matter in elliptical galaxies

The evidence for dark matter in disk galaxies is secure because their dynamics is so simple. ELLIPTICAL GALAXIES are not supported by rotation, so rotation curves cannot be used to study their dark matter content. Other dynamical mass indicators are needed. Some of the largest ellipticals are embedded in an envelope of hot x-ray emitting gas. If the radial temperature distribution of this hot gas is known, its hydrostatic equilibrium can be used to measure the total mass of the parent elliptical. The motions of stars, globular clusters and planetary nebulae in the outer regions of elliptical galaxies can also be used to estimate their masses, although this requires some assumptions about the orbits of these tracer objects. The weak gravitational lensing of background galaxies provides an interesting and independent statistical way to measure the dark matter content of elliptical and disk galaxies.

The evidence indicates that the largest elliptical galaxies contain substantial amounts of dark matter. We can use the mass-to-light ratio as a useful measure of the dark content of a galaxy. An old stellar population without dark matter has a mass-to-light (M/L) ratio of about 5 in solar units, depending on its metallicity. Disk and elliptical galaxies can have M/L ratios as high as $\sim$80. Some of the smallest elliptical galaxies, the dwarf spheroidal companions of the Milky Way, show very high dark matter content, with M/L ratios $\sim$100. For these systems, the masses are estimated from velocities measured for many individual stars. Again, some assumptions about the stellar orbits are needed.

Formation of dark halos

In the current picture of GALAXY FORMATION, clumps of dark matter mixed with baryons come together to form a galaxy. The nature of the dark matter is unknown, but it is believed to be non-dissipative. The dark halos then gradually build up into weakly flattened spheroidal structures while, in disk galaxies, the rotating baryons dissipate into flat disks in near-circular motion within their dark halos. There are now enough data on dark halos to determine how their properties change with the brightness of the visible galaxy. It turns out that the faintest galaxies have the densest dark halos, about 1000 times denser than the dark halos of the brightest galaxies. This indicates that the halos of lowest mass emerged first from the expanding universe, when the density of the universe was high, as expected from theoretical arguments.

For more information on dark matter in the universe, see the article on GALAXY CLUSTERS.

Dark Matter: Its Nature

What is the stuff that makes up most of the mass in the universe? The answer to this simple-sounding question is far from obvious, and actually presents one of the greatest unsolved mysteries of astrophysics, cosmology, and elementary particle physics. With conventional astronomical methods one can only see the 'luminous matter', notably in the form of stars, which reveals its presence by the emission of light. On the other hand, one can determine the gravitating mass of various systems such as spiral galaxies or galaxy clusters from their dynamical properties, and one finds a huge discrepancy relative to luminous matter. Assuming the usual law of gravity, one is led to conclude that there are large amounts of 'dark matter', a term first introduced by FRITZ ZWICKY in his seminal paper of 1933 where he studied the dynamics of GALAXY CLUSTERS.

The physical properties of dark matter can be constrained by several powerful astrophysical and cosmological arguments which disfavor 'baryonic matter' as a main constituent. This term refers to hydrogen, helium, and the heavier elements which, besides electrons, consist of protons and neutrons, falling into the 'baryon' category of ELEMENTARY PARTICLES. But some new form of matter appears to hold galaxies and galaxy clusters gravitationally together! The most popular explanation is that of 'particle dark matter' which goes back to Cowsik and McClelland who speculated in 1973 that neutrinos could play this role. However, while recent experiments indicate that neutrinos do have mass—which has been an open question for decades—it looks impossible to attribute all of the dark matter to these weakly interacting particles.

One is thus led to postulate hitherto undetected elementary particles for the cosmological dark matter. On the other hand, there are already independent particle-theory motivations for certain new particles which could well play this role. The dark-matter problem thus provides one of several links between particle physics and cosmology; it is a key ingredient of 'astroparticle physics', or alternatively 'PARTICLE ASTROPHYSICS'. The laws of the microcosm of elementary particles and the macrocosm of the largest structures in the universe, inner space and outer space, are closely intertwined!

Perhaps the most remarkable development of the 1990s is that the physics of dark matter has turned into a truly experimental science. If any of the popular speculations about the nature of dark matter are correct, this mysterious stuff may well turn up in one of the current or near-future direct search experiments.

In the following, the astrophysical motivation for the reality of dark matter and the most important astrophysical constraints on its nature will be discussed. Well-motivated candidates, current search strategies and preliminary results will then be reviewed.

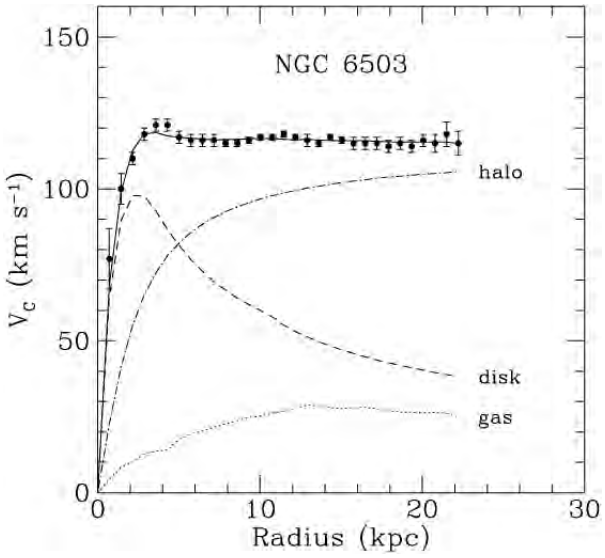

Figure 1. Rotation curve of the spiral galaxy NGC 6503 as established from radio observations of hydrogen gas in the disk (K Begeman *et al Mon. Not. R. Astron. Soc.* **249** 439 (1991)). The dashed curve shows the rotation curve expected from the disk material alone, the chain curve from the dark-matter halo alone.

Dynamical evidence

Rotation curves of spiral galaxies

Why are astronomers so sure that there are large amounts of dark matter lurking everywhere in the universe? The flat rotation curves of SPIRAL GALAXIES provide perhaps the most impressive evidence. These systems consist of a central bulge and a thin rotating disk. It is natural to measure its orbital velocity as a function of galactocentric radius by virtue of the Doppler shifts of spectral lines. Galaxy disks tend to contain neutral hydrogen which can be observed by its 21 cm line emission, allowing one to measure the rotation curves to much larger radii than with optical tracers.

The example of figure 1 illustrates the general behavior of the rotation curves. The orbital velocity rises from the center outward until it reaches a value of the order of 100 km s^{-1}, where it stays constant out to the largest measured radii, a systematic trend already diagnosed by Freeman in 1970. This behavior is entirely unexpected because the surface luminosity of the disk falls off exponentially with radius, implying that the mass M of luminous matter, mostly stars, is concentrated around the galactic center. Thus one expects a Keplerian decline of the orbital speed, $v_{\rm rot} = (G_N M/r)^{1/2}$ (Newton's constant G_N, radius r), in analogy to the planetary motions in the solar system—see the dashed line in figure 1.

The difference between the expected and measured rotation curve is ascribed to the gravitational effect of

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

dark matter. A number of arguments suggest that this material is not part of the galactic disk itself. First, in our galaxy the vertical distribution of stars together with their velocity dispersion reveals that there is no significant amount of disk dark matter. Second, a thin self-gravitating disk is dynamically unstable. Third, the hydrogen is vertically more extended than would be expected if all of the gravitating matter were in the disk, especially at large radii ('hydrogen flaring').

An overall picture of spiral galaxies emerges where the bulge and disk are dynamically subdominant components immersed in a huge dark-matter halo. It is not crucial that this halo be strictly spherical; it may well be somewhat oblate or even triaxial.

For the direct detection of dark matter, our own Milky Way is the most interesting galaxy. Its rotation curve conforms to the standard picture with an approximate plateau value for the rotation velocity of 220 km s^{-1}. The dark-matter density in the solar neighbourhood implied by models of the halo is 300MeVcm^{-3} within about a factor of two, i.e. roughly the mass equivalent of a hydrogen atom per 3 cm^3. (Note that the atomic mass unit corresponds to 931.5 MeV.)

Cosmic density contribution

The contribution ρ of a given matter component to the overall density of the universe is usually expressed in terms of the 'omega parameter' $\Omega=\rho/\rho_{\rm crit}$. Here, $\rho_{\rm crit} = 3H^2{}_0/(8\pi G_{\rm N}) = h^2\ 1.88\tilde{\rm A}$—$10^{-29}$ g cm^{-3} is the critical density with H_0 the present-day cosmic expansion parameter ('Hubble constant'). It is usually written as $H_0 = h$ 100 km s^{-1} Mpc^{-1}; different measurements span the approximate range h = 0.5–0.8. In the framework of the usual Friedmann–Lemaître–Robertson–Walker cosmology the spatial geometry of the universe is Euclidean for Ω = 1 ('flat universe'), the spatial curvature is negative for $\Omega<1$ ('open universe'), and positive for $\Omega>1$ ('closed universe').

The cosmic density contribution of galaxies is related to the measured luminosity density of the universe, (1.7 ± 0.6)–$10^8\ h\ L_\odot$ Mpc^{-3} in the visual spectral band (solar luminosity $L_\odot$). Most of the light is produced by stars; thus multiplying with the mass-to-light ratio for a typical stellar population of a few $M_\odot/L_\odot$ gives us the luminous matter density. One finds

$$\Omega_{\rm lum}h = 0.002 - 0.006$$

to be a consistent range. Therefore, luminous matter alone is far from the critical density.

Typical mass-to-light ratios of galaxy halos are at least around 30 h as far as the measured rotation curves reach, providing a cosmic density of $\Omega_{\rm gal}\gtrsim$0.03–0.05. The rotation curves tend to stay flat out to the largest measured radii and thus the true size of dark-matter halos is not known. Estimating their extent from galactic satellite dynamics yields $\Omega_{\rm gal}h$ = 0.2–0.5.

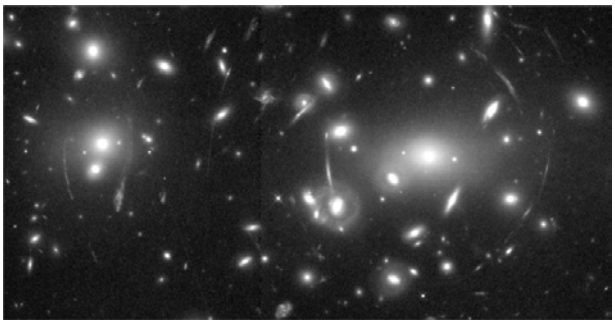

Figure 2. Hubble Space Telescope image of the galaxy cluster Abell 2218, showing a number of arcs and arclets around the two centers of the cluster. They are distorted images of background galaxies, caused by the cluster's gravitational lens effect. (NASA HST Archive.)

Clusters of galaxies

Galaxy clusters are the largest gravitationally bound systems in the universe. Zwicky first noted in 1933 that the velocities of the member galaxies tend to be so large that huge amounts of dark matter are needed to bind them gravitationally. Taking a cluster mass-to-light ratio of around 300 $M_\odot/L_\odot$ as representative for the universe leads to a cosmic matter density of $\Omega_{\rm M}$ = 0.1–0.4.

Recently it has become possible to measure cluster masses from the image distortion of background galaxies caused by the cluster's gravitational light deflection ('weak gravitational lensing'); an example is shown in figure 2. One uses the statistical distribution of these 'arclets' to reconstruct the shear field of gravitational image distortions and from there one can derive cluster mass distributions. (see GRAVITATIONAL LENSISNG BY CLUSTERS OF GALAXIES). They confirm the large mass-to-light ratios inferred by Zwicky's method.

When X-RAY TELESCOPES became available in the mid-1960s, galaxy clusters were found to be the most powerful x-ray sources in the sky. The emission is extended over the entire cluster and thus reveals the presence of large amounts of hot gas ($T = 10^7$–10^8 K) where x-rays are produced by electron bremsstrahlung. The mass in this 'x-ray gas' is typically 10–20% of the total, i.e. clusters contain more mass in hot gas than in stars. Detailed studies reveal a cluster baryon fraction of typically $f_{\rm B}h^{3/2}$ = 0.03–0.08.

Large-scale flows

On large scales the motion of galaxies is dominated by the overall cosmic expansion. Still, they exhibit 'peculiar velocities' relative to the overall cosmic flow; our group of galaxies moves at 627±22 km s^{-1} relative to the reference frame defined by the cosmic microwave background radiation. These motions are attributed to the action of gravity over the age of the universe, caused by the inhomogeneities of the matter density. The observed large-scale velocity fields, together with the observed

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

galaxy distributions, are then translated into a measure for the matter density required to explain the large-scale flows. One finds

$$\Omega_M > 0.3$$

and even larger values by related methods which are more model-dependent.

Flat universe

The critical value $\Omega_{tot} = 1$ for the cosmic mass–energy density, corresponding to an overall Euclidean (flat) spatial geometry, is favored to avoid fine-tuning the cosmic initial conditions. In an expanding universe, Ω_{tot} quickly evolves away from 1 towards either 0 or ∞ so that the near-flatness of the present-day universe suggests $\Omega_{tot} = 1$ as an exact identity. Moreover, 'inflationary models' of the early universe generically produce a flat geometry even though one can construct specialized models which circumvent this outcome. The critical density exceeds the luminous mass by about two orders of magnitude so that the universe, if it is flat, contains more than 99% dark matter.

Astrophysical constraints

Big-bang nucleosynthesis

The first question about the nature of dark matter is whether it could not consist of ordinary material in some non-luminous form, perhaps stellar remnants such as neutron stars or molecular hydrogen clouds which are difficult to observe. However, the overall baryon abundance is severely constrained by big-bang NUCLEOSYNTHESIS.

When the universe was about three minutes old, the initial protons and neutrons formed helium at a mass fraction of about 22–25%, together with some traces of deuterium (D or ^{2}H), ^{3}He and ^{7}Li. Within the standard big-bang picture, these primordial light-element abundances depend only on the cosmic baryon density (see BARYOGENESIS).

The abundance most sensitive to $\Omega_B h^2$ is that of deuterium. Its measurement in intergalactic hydrogen clouds has recently become possible by observing quasar absorption lines. While this novel approach holds much promise toward a precision determination of the primordial deuterium abundance, one currently finds both high and low values of $D/H \div 2\text{–}10^{-4}$ and $2\text{–}10^{-5}$, respectively, which are mutually inconsistent unless the baryon distribution is vastly inhomogeneous on large scales. They span a range roughly corresponding to

$$\Omega_B h^2 = 0.005 - 0.024$$

which is consistent with the helium and lithium observations. The more favored low deuterium value corresponds to a high baryon content.

This range for Ω_B is depicted in figure 3 as a function of the Hubble expansion parameter together with the luminous mass density of (1) and the lower dynamical mass limit of (2). The currently favored range for H_0 is 50–80 km s^{-1} Mpc^{-1}, implying a gap between the cosmic baryon density and both the luminous and the dynamical matter density. Apparently there is a significant fraction of 'dark baryons' which never made their way into galaxies and stars, and more importantly, lots of unidentified non-baryonic dark matter. The apparent gap between the baryons and the dynamical mass density corresponds well to the baryon fraction implied by the x-ray gas in galaxy clusters discussed earlier.

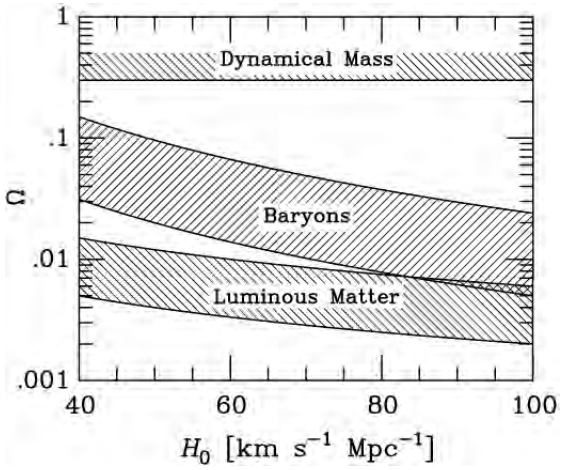

Figure 3. Cosmic matter components as a function of the assumed present-day Hubble expansion parameter.

Structure formation

The standard theory of cosmic structure formation holds that at some early time the universe was almost perfectly homogeneous, apart from tiny density modulations, which were enhanced by the action of gravity as time went on, leading to the formation of galaxies, clusters, and large-scale coherent structures. It is often argued that the primordial density variations came from quantum fluctuations in the very early universe which were boosted to macroscopic scales during a phase of exponential expansion ('INFLATIONARY UNIVERSE').

The amplitude of the density fluctuations at the epoch when the COSMIC MICROWAVE BACKGROUND radiation decoupled from the ambient plasma has now been inferred from several experiments, notably the COBE satellite, which measured the temperature fluctuations across the sky. An amplitude of the fluctuation spectrum consistent with these measurements is too small to allow the observed structures to form if the medium consists only of baryons and radiation. Weakly interacting particles fare better because they are not held up by photon pressure ('dark-matter boost'). This is a generic argument against baryonic dark matter even though there may be possibilities to circumvent it.

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

The matter which makes up the cosmic 'fluid' can diffuse, wiping out part of the initial density fluctuations. This effect is particularly important for weakly interacting particles which can diffuse far until their momentum has been sufficiently redshifted by the cosmic expansion; they erase the primordial fluctuation spectrum up to a scale which is larger for less massive particles. One speaks of 'hot dark matter' if the fluctuations are wiped out below scales which later correspond to galaxies, while 'cold dark matter' has this effect only on subgalactic scales. The dividing line ('warm dark matter') corresponds to a particle mass in the keV range.

The consensus is now almost universal that some variant of a cold dark matter scenario is probably how our universe works, where structure forms by the gravitational instability mechanism from a nearly scale-invariant spectrum of primordial density fluctuations. It strongly disfavors both baryons and low-mass particles such as massive neutrinos as the main ingredients of the cosmic matter cocktail.

Cosmic microwave background

The cosmic microwave background radiation holds a wealth of cosmological information. Its very presence and its uncannily precise black-body nature are the most striking proofs of the hot big-bang cosmogony. The COBE satellite and more recent ground-based experiments have measured tiny angular temperature variations with typically 10 μK amplitudes which already provide tight constraints on theories of structure formation and thus on the nature of dark matter.

The most important information is contained in the power spectrum of the temperature sky map. While there is still a lot of scatter in the data, they already seem to confirm the appearance of features known as 'acoustic peaks' or 'Doppler peaks'. Their angular scale and amplitude provide invaluable information on the properties of the universe at radiation decoupling.

There are two approved satellite missions, NASA's Microwave Anisotropy Probe (MAP), to be launched in 2001, and ESA's PLANCK, to be launched around 2007, which will take full-sky temperature maps at fine angular resolutions. It is thought that these experiments will ultimately be able to determine the most important cosmological parameters on the 1% level, notably the baryon fraction and total dark matter content. There remain degeneracies between different combinations of parameters, however, which will need to be broken by other methods.

Candidates and searches

Neutrinos

The presence of large amounts of dark matter in the universe is almost uncontroversial, and the case against baryons as a main component is quite compelling, leaving us with particle dark matter (PDM) as one possible solution. The candidate particles would have to be relics from the early universe where they would have been produced thermally in the hot and dense plasma, or by some non-equilibrium process.

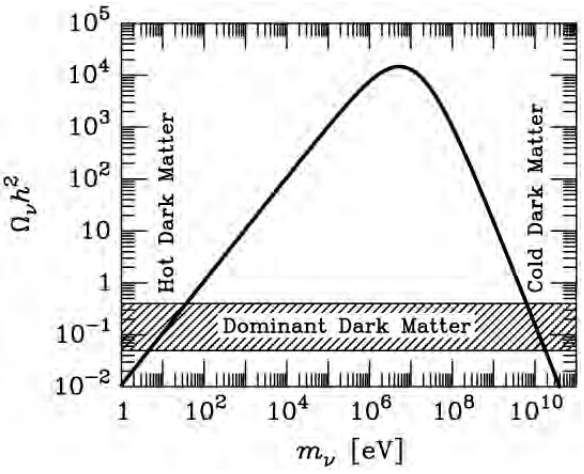

Figure 4. Cosmic mass density as a function of the assumed neutrino mass ('Lee–Weinberg curve'). The hatched band indicates the required range for Ωh^2 of the dominant particle dark matter component.

The minimum required relic density is $\Omega_{\rm PDM} \gtrsim 0.2$ if we use (2) and allow for a significant baryon fraction. The observed age of the universe together with the measured expansion rate yields $\Omega h^2 \gtrsim 0.4$ so that

$$\Omega_{\rm PDM} h^2 = 0.05 - 0.4$$

where $h \gtrsim 0.5$ has been used.

Of the known particles, neutrinos are the only candidates. Their relic density as a function of the assumed mass is shown in figure 4. There are crudely as many background neutrinos in the universe as there are microwave photons. Multiplying this number by m_ν explains the increasing branch of figure 4 and gives $\Omega_\nu h^2 = \sum m_\nu / 93$ eV, whence the required neutrino mass is 4–40 eV. There is a second solution for a neutrino mass of a few GeV on the decreasing branch; the number of relic neutrinos is reduced by annihilations for $m_\nu \gtrsim 1$ MeV, where they are still in thermal equilibrium when the cosmic temperature falls below their mass.

The laboratory limit of about 20 MeV for ν_τ, and much less for ν_μ and ν_e, precludes the large-mass solution among the known neutrino families. The low-mass solution, however, is problematic from the perspective of structure formation because they represent 'hot dark matter'. In addition, there is a problem with neutrinos filling the dark-matter halos of galaxies as they cannot be arbitrarily densely packed in phase space. This 'Tremaine–Gunn argument' requires $m_\nu \gtrsim 20$ eV for typical spiral galaxies, and a few 100 eV for dwarf galaxies so that neutrinos could not be the dark matter on all scales.

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

Finally, the positive evidence for neutrino masses from recent oscillation experiments points to sub-eV mass differences between the three flavours so that their masses would have to be much larger than their differences ('degenerate masses') if they were to be dark matter. The largest cosmologically allowed mass of about 40 eV then distributes itself among the three families so that each of them must be lighter than about 13 eV, exacerbating the Tremaine–Gunn problem.

Weakly interacting massive particles (WIMPs)

Neutrinos on the decreasing branch in figure 4 would play the role of cold dark matter and are thus favored by cosmology, but in this mass range they do not exist. One thus postulates novel weakly interacting massive particles (WIMPs; see WIMPS AND MACHOS) to fill the gap. On the other hand, from a theoretical perspective one postulates a 'SUPERSYMMETRY' which predicts a new partner to every known particle. The lightest supersymmetric particle in the form of a 'neutralino' could well play the WIMP role. Independently of the dark-matter problem, the search for supersymmetry is one of the main goals of the most ambitious particle accelerator ever, the Large Hadron Collider (LHC) which is currently under construction in Geneva at the CERN Laboratory.

If the dark matter consists of some form of WIMPs, then our Milky Way galaxy should be filled with a 'gas' of these almost collisionless particles which would permeate everything, including our laboratories. The experimental search for galactic WIMPs has turned into an entire branch of non-accelerator particle physics, with numerous groups mounting more and more sensitive detectors. Usually one tries to measure the tiny energy depositions caused by a rare collision of a galactic WIMP with a nucleus in a crystal. In semiconductor crystals, especially germanium, one searches for the resulting electronic signal, in sodium iodide crystals for the scintillation light, or one may cool the crystal to very low temperatures and search for the minuscule heating caused by WIMP collisions; an example for such a cryogenic setup is shown in figure 5.

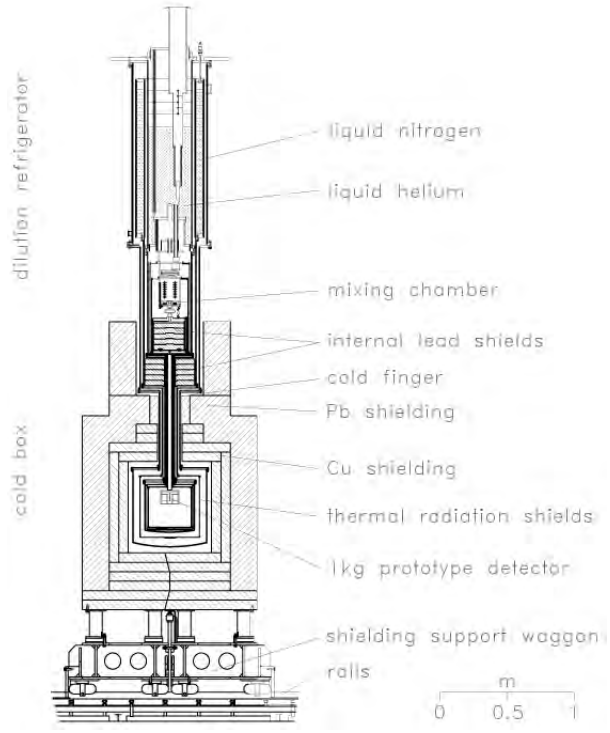

Figure 5. Schematic view of the experimental setup of CRESST, located in the Gran Sasso underground laboratory near Rome (Italy), as an example for a cryogenic dark-matter experiment.

The main experimental problem is the extremely small expected signal rate. In detail, it depends on the assumed WIMP properties and target material, but a typical number is below 1 event kg^{-1} d^{-1}. To reduce natural radioactive contaminations one must use extremely pure substances, and the cosmic-ray background requires locations deeply underground, for example in deep mines.

There exist other 'indirect' search methods. For example, WIMPs traversing the Sun or Earth will occasionally collide with a nucleus there, lose enough energy to get trapped, and ultimately annihilate with other trapped WIMPs. The resulting high-energy neutrinos from the Sun and the center of the Earth may well show up in existing and future neutrino telescopes.

While supersymmetric models are quite flexible in their predictions, the current round of experiments has reached the sensitivity where one can begin hoping to find these elusive dark-matter candidates.

Axions

A cold dark matter candidate *sui generis* is provided by axions, low-mass bosons which are postulated in the framework of quantum chromodynamics, the theory of the strong interaction among quarks. Other than neutrinos and WIMPs, these particles would arise from a non-thermal process in the early universe, producing essentially a Bose condensate, i.e. highly occupied, quasi-classical oscillations of the axion field. The axion mass would lie in the 10^{-5} eV regime, corresponding to GHz oscillation frequencies of the axion field.

Axions would have tiny electromagnetic interactions, implying that galactic dark-matter axions would drive a microwave cavity, provided it is placed in a strong magnetic field. Two such experiments are now in operation, one in Livermore, California (US Axion Search), the other in Kyoto, Japan (CARRACK). Their sensitivity is enough to detect the feeble output of a microwave cavity, induced by galactic dark-matter axions. Again, within the next few years one has a realistic chance to detect dark matter if the underlying hypothesis of the existence of axions is correct.

Dim stars (MACHOs)

As long as particle dark matter has not been found, one may continue to speculate that the arguments against baryons are wrong and that galactic halos consist of ordinary matter in some non-luminous form. Obvious candidates are dim stars which have been termed massive astrophysical compact halo objects (MACHOs) as a deliberate pun on the WIMP hypothesis.

The physical nature of MACHOs could be stars which are too small to shine brightly (brown dwarfs or M dwarfs) or burnt-out stellar remnants (WHITE DWARFS, NEUTRON STARS, BLACK HOLES). Of course, stellar remnants seem implausible, among other reasons because they would have to arise from a large population of normal stars, of which there is no trace in the halo.

A practical search method involves the gravitational light deflection caused by a galactic MACHO which happens to pass near the line of sight to a background star. While the effect is too weak to produce several resolved images of the target star, its apparent brightness will temporarily increase because the MACHO's gravitational field effectively focuses more light into the telescope ('gravitational microlensing'). Such events are rare so that one must monitor millions of stars simultaneously to obtain a reasonable event rate. The Large and Small Magellanic Clouds as target regions have enough bright stars at a suitable distance and have been used since the early 1990s by the MACHO and EROS Collaborations in an attempt to find non-luminous stars making up the Milky Way halo.

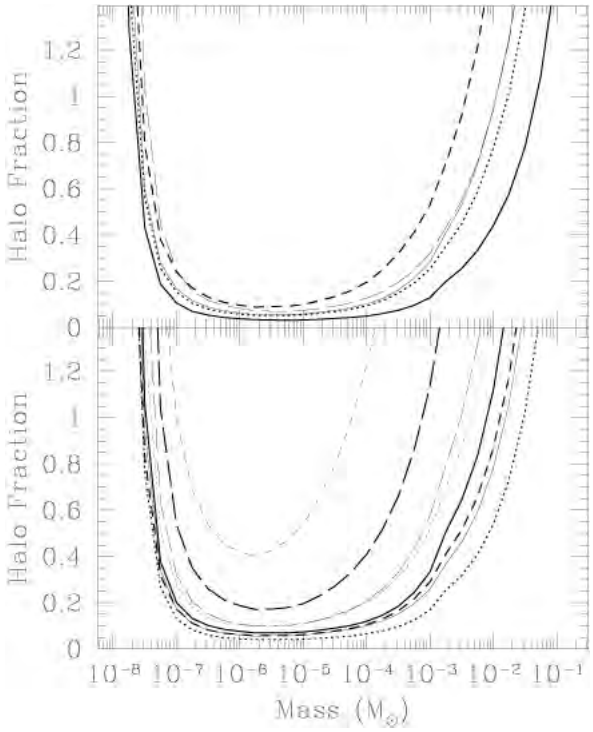

Figure 6. Upper limit to the Milky Way halo fraction that can be attributed to MACHOs as a function of their assumed mass from a combined analysis of the MACHO and EROS data. The different line styles correspond to different halo models; the upper panel shows those used by the EROS Collaboration, while the lower panel the ones of the MACHO Collaboration. In each case the solid curve represents a 'standard halo'. (C Alcock *et al Astrophys. J.* **499** L9 (1998).)

The duration of the temporary brightness excursion of a lensed star depends on the relative distances between observer, lens and target star, and on the lens mass. The non-observation of short-time events has allowed these experiments to exclude MACHOs over a wide mass range as a dominant halo component (figure 6), but does not yet exclude brown dwarfs as a possibility.

On the other hand, about a dozen positive events have turned up which, if attributed to MACHOs, would point to a mass around 0.5 $M_\odot$. However, the early excitement about the apparent discovery of some or all of the galactic dark matter has given way to a more sceptical assessment—the apparent mass range of the observed events simply does not seem to make sense. Perhaps the least troubling interpretation is that one is not seeing MACHOs but normal stars as lenses, which is possible if there is an unrecognized population of stars between us and the Large Magellanic Cloud, or even by stars within the Magellanic Clouds themselves if their distribution is different from what had been thought. Thus, while the observed MICROLENSING events are no doubt real, the question of where and what the lenses are remains for now wide open. (See also DARK MATTER IN GALAXIES.)

Primordial black holes

While stellar remnants seem implausible, black holes which formed in the early universe cannot be excluded as dark-matter candidates. From a structure-formation perspective, they represent cold dark matter; from a search perspective, they could be MACHOs. The main objection is the lack of a plausible production mechanism in the early universe. Surely, as long as particle dark matter remains undiscovered, and as long as the observed microlensing events remain unexplained, primordial black holes should not be brushed aside.

Cosmological constant (vacuum energy)

It is possible, and indeed implied by particle physics theory, that gravitating energy is associated with the ground state of quantum fields, i.e. with the vacuum. In the equations of general relativity it would play the role of a 'COSMOLOGICAL CONSTANT', an optional term which is permitted by the symmetries of the equations, but which is not motivated by the Newtonian limit. Vacuum energy would form a perfectly homogeneous background and thus cannot explain galactic rotation curves or dark matter in galaxy clusters. On the other hand, it could well explain the gap between dynamical measures of dark

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

matter and the critical density (figure 3). We could have a Euclidean universe even if 'real matter' contributes only a sub-critical mass density.

The most counterintuitive property of vacuum energy is that it is not diluted by the cosmic expansion but rather becomes more and more dominant relative to normal matter as time goes on. It cannot be measured locally; a modification of the cosmological redshift–distance relationship is the main observable consequence.

Type Ia SUPERNOVAE as standard candles at cosmological distances have recently provided some exciting evidence for a cosmological constant. While being far from definitive, it suggests that the universe could be Euclidean with something like 70% of the critical density in vacuum energy and 30% in matter. This scenario accommodates effortlessly the absolute and relative amounts of baryonic and non-baryonic matter implied by big-bang nucleosynthesis, the x-ray gas in galaxy clusters, dynamical indicators for dark matter, and a flat geometry of the universe.

Modified gravity

The hypothesis of particle dark matter requires non-trivial and perhaps bewildering extensions of the standard model of particle physics. As long as the nature of dark matter has not been positively identified it may seem no more radical to modify general relativity such that there is no need for dark matter. It has sometimes been argued that the hypothesis of dark matter is just a parameterization of our ignorance of the physical laws which apply on large astrophysical scales where no independent tests of the validity of general relativity exist.

In one phenomenological approach known as modified Newtonian dynamics (MOND), gravitational accelerations a below a certain limit a_0 are given by $a^2/a_0 = G_N M/r^2$ (Newton's constant G_N). With $a_0 \approx 10^{-10}$ m s^{-2} this approach is surprisingly successful at explaining a broad range of dark-matter phenomena related to dwarf galaxies, spiral galaxies and galaxy clusters. Unfortunately, MOND lacks a relativistic formulation so that it cannot be applied in a truly cosmological sense.

Before modifications of general relativity can be taken seriously they must pass relativistic tests. An important case are galaxy clusters where large amounts of dark matter are indicated by non-relativistic methods *à la* Zwicky (virial theorem) as well as by relativistic indicators (gravitational lensing). As virial and lensing masses seem to agree well in several cases, scalar–tensor extensions of general relativity are in big trouble, if not ruled out entirely.

No serious attempt has been made to discuss truly cosmological phenomena such as structure formation and microwave background temperature fluctuations in the framework of alternative theories of gravity. At present no covariant theory of gravity is known that can explain the dark-matter problems on all scales.

Conclusion

Over the past decade, the idea has become almost commonplace that most of the stuff in the universe consists of non-baryonic matter, perhaps in the form of neutralinos or axions which are motivated in particle physics for independent reasons. Yet this remains a radical conjecture which has often been likened to the Copernican revolution when Earth and with it Man was moved from the center of creation to some unspectacular average position. Probably the next big step in this second Copernican revolution will be precise measurements of the angular temperature fluctuations of the cosmic microwave background, which are expected to confirm or refute the apparent discrepancy between the baryon content of the universe and its dynamical mass density. Even then, however, the second revolution will not be complete without a direct and positive identification of the dark-matter particles or objects. Until that happens, perhaps by one of the ongoing experimental searches, one should keep an open mind. The true solution of the dark-matter problem may not have been thought up yet.

Web update (31 July 2002)

A team of 27 astronomers led by Professor George Efstathiou of the University of Cambridge has published strong evidence for the existence of dark energy using the clustering pattern of 250 000 galaxies in a large volume of the universe surveyed with the Anglo–Australian Telescope at Siding Spring in New South Wales, Australia. By comparing the structure in the universe now, some 15 billion years after the Big Bang, with structure observed in the cosmic microwave background radiation, which preserved information about what the universe was like when it was only 300 000 years old, the Anglo–Australian team could apply a simple geometrical test to elucidate the composition of the universe. Their results show that the universe is full of vacuum energy, completely consistent with the earlier supernovae results.

Christopher Kochanek of the Harvard–Smithsonian Centre for Astrophysics in Cambridge, Massachusetts and Neal Dalal of the University of California, San Diego have used radio telescopes and gravitational lensing to search for cold dark matter. They have studied seven galaxies, each magnified by four nearer ones. Because each lensing galaxy is in a slightly different position, the researchers got four different images of each of the seven distant galaxies. The four images should have been identical. But each is actually slightly different. The difference was enough to have been caused by the kind of clumps of dark matter around lensing galaxies that mathematical models predict.

Dark Nebula

An interstellar cloud of gas and dust which absorbs light from nearby sources, also known as an *absorption nebula*; the light is re-emitted as infrared radiation or scattered, making the nebula appear dark. At higher galactic latitudes, away from the Milky Way, dark nebulae appear merely as particularly star-poor regions of the sky, but near or against the Milky Way they show up strongly in contrast with the bright star fields around them. Prominent dark nebulae seen in silhouette against the Milky Way are the Cygnus Rift in the northern hemisphere and the Coalsack in the southern. A small but strikingly distinctive dark nebula is the famous Horsehead nebula in Orion. The smallest are known as globules. Dark nebulae consist predominantly of molecular hydrogen and are believed to be sites of star formation. The true nature of dark nebulae—that they are not simply voids—was first recognized by E E Barnard, who photographed and cataloged them; the results were published in 1927 in *A Photographic Atlas of Selected Regions in the Milky Way*. A more comprehensive catolog of dark nebulae by Beverly Lynds appeared in 1962.

Darwin, George Howard (1845–1912)

Mathematician and astronomer, born in Downe, Kent, England, a son of Charles Darwin, became Plumian professor of astronomy and experimental philosophy at Cambridge University. He applied mathematical theory to the dynamics of the Sun–Earth–Moon system. He added physical effects into gravitational theory, including the frictional effects of tidal action and the shapes which the Earth and Moon take up as they rotate. From his work, he proposed a theory of the origin of the Moon, namely that it was pulled from a molten Earth early in its history by tidal action of the Sun, the first time that the origin of a planet had been explained from its current dynamical state.

Davenport, William (1782–1823)

Irish astronomer, born in Dublin, became the second director of the Armagh Observatory. During eight fruitless years of idleness and decline he contributed practically nothing to astronomy until he committed suicide with a shotgun in the study of the observatory.

David Dunlap Observatory

The David Dunlap Observatory (DDO) is located 25 km north of the center of Toronto, Canada, in the town of Richmond Hill at 79d 25′ 20″W and +43d 51″ 46″N. Operated as a research and educational facility of the Department of Astronomy at the University of Toronto, DDO is the site of a 1.88 m reflecting telescope, the largest in Canada. Two smaller telescopes plus computer, library and support facilities are available for the use of astronomers. The observatory was made possible with a generous donation by the Dunlap family in June 1928 through the efforts of the first director Clarence A Chant. First light for the 1.88 m telescope occurred on the night of 31 May 1935.

The telescope has remained in productive use to the present day contributing to research in several areas including: determining the radial velocities of stars in the solar neighborhood; pioneering work on Cygnus X-1, the first detected black hole candidate; cataloging of globular clusters; analyses of several classes of variable stars, especially Cepheid, RR Lyr-type and close-binary stars; and studies of the galactic interstellar medium. The 1.88 m telescope has been upgraded with computer controls and modern instrumentation and is dedicated to spectroscopic studies of mainly galactic objects. A variety of public programs, courses and school visits are also offered at DDO.

For further information see
http://ddo.astro.utoronto.ca/ddohome.

Dawes, William Rutter (1799–1868)

English clergyman and keen-eyed amateur astronomer. Observed double stars, discovered Saturn's Crêpe Ring independently of WILLIAM BOND. Gave a useful empirical formula for the resolving power of a telescope known as *Dawes limit*: for a telescope of aperture d cm a double star of separation $11/d$ arcseconds or more can be resolved.

Dawes' Limit

An empirical measure of the resolving power of a telescope that was devised by William Rutter Dawes (1799–1868), a keen-eyed observer of double stars. According to the Dawes' criterion, the resolving power of a telescope is given by $R = 0.115/D$, where R denotes resolving power expressed in seconds of arc and D denotes the aperture of the telescope (in meters). For example, the Dawes' limit for a telescope of 0.1 m (100 mm) aperture would be $0.115/0.1 = 1.15$ arcsec. The Dawes' limit gives resolving powers that are some 20% better that the theoretical values that are given by the Rayleigh limit. This reflects the fact that skilled observers, under ideal conditions, may be able to resolve double stars that are marginally closer together than the theoretical limit, a limit that is defined in a convenient, but to some extent arbitrary, fashion.

See also: aperture, Rayleigh limit, resolving power.

Day

Traditionally, the time taken for the Earth to rotate once around its axis, but conventionally taken to be 86 400 SI seconds unless otherwise specified. There are several different definitions of the day. The sidereal day is the time interval between two successive upper transits of the vernal equinox; it is, in effect, the time taken for the Earth to rotate on its axis through an angle of 360° with respect to the background stars. The apparent solar day is the time interval between two successive noons (upper transits of the Sun across an observer's meridian). Because (a) the Earth moves round the Sun in an elliptical orbit at a variable rate, and (b) the apparent annual path of the Sun relative to the stars (the ecliptic) is tilted at an angle to the celestial equator, the right ascension of the Sun changes at a non-uniform rate and the time interval between successive noons (and hence the duration of the apparent solar day) is not precisely constant. The mean solar day is the time interval between two successive upper transits of a hypothetical object called the mean sun, which moves along the celestial equator, relative to the background stars, at a uniform rate (equal to the average angular rate at which the real Sun appears to move along the ecliptic). On the assumption that the Earth rotates on its axis at a uniform rate (which is not strictly accurate), mean solar days are of equal duration.

Because the Earth revolves round the Sun at an average angular rate of just under 1° per day, the Earth has to rotate through an angle of nearly 361° between successive upper transits of the Sun across an observer's meridian. Consequently, the mean solar day is just under 4 min longer than the sidereal day and the sidereal day is equal to 23 h 56 min 04 s of mean solar time.

DB Pulsating Stars

Pulsating WHITE DWARF stars with nearly pure helium atmospheres exist in a narrow temperature range near 25 000 K. At this writing, there are eight of these stars known. Collectively, they go by two names: the V777 Her stars, named after the VARIABLE STAR designation of the first known star in the class, and the more informative name, the DBV stars. The name DBV follows the standard convention for white dwarf stars and tells us that they are of spectral type DB, indicating a nearly pure helium atmosphere, and the V suffix indicates they are variables of that spectroscopic class; this is how we will refer to them.

The STELLAR PULSATIONS in the DBV stars are global in nature; their study provides a window into the deep interiors of these dense stars, and thereby a chance to learn about the physics of matter under extreme conditions of density and temperature inaccessible in terrestrial laboratories.

Stars that begin their lives with total masses below about $10M_{\odot}$, or well over 90% of all stars, end their lives as white dwarf stars. Of these, roughly 30% will become DB white dwarf stars. Since the DBV stars are otherwise normal, anything we learn about their internal structure applies to other DB stars as well. Studies of the DBV stars thereby serve to constrain our understanding of one of the two most significant endpoints for STELLAR EVOLUTION. This is of increasing importance as we are learning to use calculations of the ages of the cool white dwarf stars as chronometers to measure the ages of the various STELLAR POPULATIONS in the galaxy.

The DBV stars are particularly significant to the more than 300 yr old science of pulsating variable stars in that they are the first class of pulsating variable stars whose existence was predicted theoretically prior to their discovery. Recently, the pulsating subdwarf B stars joined the DBV stars in the distinction of being predicted in advance of their discovery. Together they indicate the rapid advances in our understanding of pulsating variable stars.

What we know about the DB pulsators

The DBV stars share a set of common observed properties with the other classes of pulsating white dwarf and pre-white-dwarf stars, the DOV (PG 1159-035, GW Vir) stars, the PNNV stars, and the DAV (ZZ Ceti) stars. The observed pulsations occur on timescales of 100–1000 s and are the result of modulations in the total intensity of the starlight. The amplitudes range from the limits of detectability at or near 1 part in 10 000 up to 30%. Typical amplitudes of the peak-to-peak variations in the light curves are of order 10% and appear to be modulated on timescales of days to years. All objects are multiperiodic with complex light curves. The top panel in figure 1 is a portion of a typical light curve of the DBV prototype, GD 358 (V777 Her).

The similarities in observed properties of all of the pulsating white dwarf and pre-white-dwarf stars are reflected in similarities of the theoretical interpretations. The largest-amplitude frequencies present in the light curves are the normal modes of oscillation of the star. The frequencies of the normal modes are consistent only with the class of non-radial pulsation modes known as g-modes. These modes have gravity as their restoring force and are characterized by fluid motions of the star primarily along gravitational equipotential surfaces. Modes with relatively small radial displacements are energetically more favorable for high-gravity objects such as white dwarf stars. The high gravity combined with relatively slow rotation rates, and the absence of strong magnetic fields, makes the stars almost completely spherical. Just as in all spherical potential problems in physics, such as the familiar quantum mechanical description of the atom, spherical harmonics provide an appropriate representation of the normal modes of oscillation in the white dwarf stars.

In all of the non-radial pulsating stars, similarly to energy levels in the atom, the frequency of each observed mode is associated with three quantized numbers, k, l and

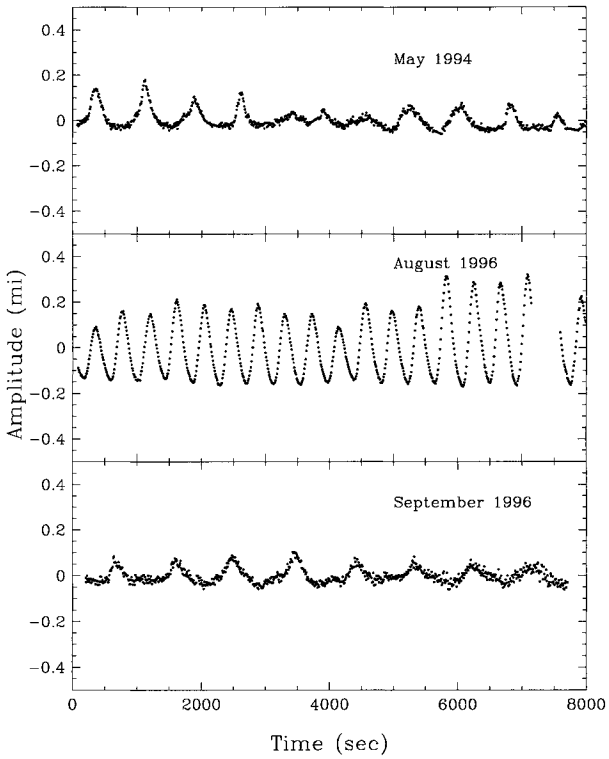

Figure 1. Portions of light curves of the DBV prototype GD 358 (V777 Her). The top panel is a typical light curve from the 17 yr it has been observed. The middle panel is a portion of the light curve during a surprising event when one of the lower-amplitude pulsations completely dominated the light curve with a very large amplitude and a nearly perfectly sinusoidal pulse shape. The lower panel illustrates the return to more normal appearing light curve after this event.

m:

$$\sigma = \sigma_{k,l,m}$$

The first of the quantized numbers, k, corresponds approximately to the number of radial nodes in the eigenfunction, the second to the degree (sometimes referred to as the order) of the spherical harmonic and the third is the azimuthal quantum number. For a completely spherical system, the frequencies of the modes are degenerate with respect to m. In a real star this degeneracy is likely to be broken by non-zero rotation or possibly a magnetic field.

We can visualize the degree as the number of nodal circles passing around the star. At the photosphere this divides the star into alternating bright and dark regions which give rise to the observed light intensity variations. Because we are observing the whole disk, the alternating regions are averaged over the disk. This causes a geometric cancellation of the bright and dark regions making it difficult, or impossible, to observe intensity variations for $l \geq 5$ with current detectors. We note that spectroscopic techniques of Doppler mapping used in other bright non-radial pulsators are not possible here because the white dwarfs are both fainter and broad lined. This is even more acute for the DBV stars because the helium lines do not have the sharp NLTE core we observe in the hydrogen lines in the DAV stars. See also NON-RADIAL STELLAR PULSATIONS.

Theoretical calculations of the origin of the observed modes suggest that they are self-excited, or amplified from small perturbations always present in the star, and that the physical process responsible for the self-excitation is associated with the partial ionization of the helium in the surface layers. The nature of this excitation and its relation to the convection associated with the partial ionization are difficult problems currently being explored. Our understanding of this process is in its infancy.

Asteroseismology of the DB white dwarf pulsators

The theoretical calculation of the eigenfrequencies for models of the DBV stars, as for the other white dwarf and pre-white-dwarf pulsators, can be carried out to considerable accuracy in the adiabatic approximation. This neglects the change in energy of a mode and is for the most part independent of the detailed structure of the partial ionization zone and any dynamical processes taking place there. Because time is the quantity we can measure most accurately in science, frequencies are also the most reliable of the quantities we measure observationally for the pulsating variable stars.

The accuracy in both the measurement and the calculation of frequencies lends itself to their intercomparison as a way to learn about the internal structure and evolution of the stars. This process is called asteroseismology.

Using the techniques of asteroseismology we have made significant progress in measuring the total mass, surface layer structure, rotation rate and law, magnetic field strength and the absolute luminosity of the DBV stars. This last gives us an important asteroseismological distance measure.

Our expectation, based on the linear theory, is that for each degree, l, we should find a series of multiplets, corresponding to different radial overtones, each with $2l+1$ components. The separation between the different modes of the multiplets is related to the rotation rate of the star and is a weak function of l. This should give us an independent measure of the rotation rate of the star for each l observed. The spacing between the periods of the multiplets of different radial overtone is set, as you might expect from the nature of the restoring force for g-modes, by the buoyant frequency averaged over the star, weighted by the eigenfunctions. This spacing is roughly uniform in period, and the average value provides a sensitive determination of the mass of the star.

Deviations in the spacing of consecutive modes from the average value are caused by the way that the eigenfunctions sample the star. This is strongly influenced by the compositional layering of the star that has resulted from its prior nuclear burning history augmented by chemical diffusion in the strong gravitational field. This stratification produces resonant mode trapping, which leaves its signature in periodic variations of the spacings of the modes from the global average. This pattern in the frequency distribution is called a trapping cycle and its determination makes possible an accurate measure of the surface layer chemical stratification.

Asteroseismological analysis depends on accurate measurements of all of the frequencies present in the star. The more frequencies present the greater the potential scientific return. Fortunately most of the DBV stars are quite rich in observed frequencies; however, this richness exacts a price. In order to disentangle the many closely spaced frequencies it is necessary to observe with as few gaps in the data as possible for a period long enough to resolve the multiplets.

To accomplish this task for pulsating white dwarf stars and related objects, the WHOLE EARTH TELESCOPE (WET) network was established in the late 1980s and is currently in operation. This network uses many optical facilities around the globe to provide essentially continuous coverage of a selected target. Telescope time allocation constraints and the phase of the Moon typically set the total length of these observing runs—new Moon is required because the white dwarf stars are typically quite faint. The concept is to defeat the encroachment of daylight at any one sight: a kind of an anti-British-Empire where we would say 'The Sun never rises on the Whole Earth Telescope'.

To date, the most extensively observed DBV star is the prototype star, GD 358 (V777 Her). Nearly 150 h of continuous WET observations made possible accurate determinations of the total stellar mass, surface He-layer mass, luminosity and the distance to GD 358. The best fitting values were $(0.61 \pm 0.3) M_{\odot}$ for the total stellar mass, -5.70 $(+0.18 - 0.30)$ for the logarithm of the fractional He-layer mass, $\log(L/L_{\odot}) = -1.3$ $(+0.09 - 0.12)$ for the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

luminosity and a distance of 42 ± 3 pc. For GD 358 we also have an observed parallax value of 36 ± 4 pc. For now, we have these impressive results for only one DBV, but results based on observations of more DBV stars with the WET should follow in the next several years.

Mysteries for the future

With all the progress we have made in understanding the frequencies and their distributions in the DBV stars, we have made very little progress in understanding the pulse shapes in the light curves. All but one currently known has a pulse shape with sharp maxima and broad flat minima (see the top and bottom panels of figure 1 for an illustration of the shapes of the typical pulses). These pulses are very asymmetric about the mean light level as well as being non-sinusoidal. Many linear combination frequencies (for the most part first sums and differences with the sums having the highest amplitudes) are often present with much higher amplitude than the actual harmonics of the modes. The cause, if we can find it, holds a clue to the physics of the pulsations and in particular their excitation.

We have also observed changes of an order of magnitude or more in the relative amplitudes of particular modes. Perhaps the most dramatic instance of this came during simultaneous Hubble Space Telescope and ground-base observations of GD 358, when a single mode rose to amplitude of 30% and assumed a completely sinusoidal pulse shape. A sample from this light curve is in the middle panel of figure 1. The timescale on which this occurred was of order a day, and the timescale to return to its more normal multiperiodic light curve was of the same order. A portion of the light curve after the more normal behavior resumed is shown in the bottom panel of figure 1. What is the cause of these dramatic changes? Are they periodic? We simply do not yet know, but the answer should prove to be exciting.

One of the most vexing problems in the DBV stars is the role of convection in determining the pulsation properties. The convective turnover times near the top of the convection zone are estimated to be of order 1 s, very short compared with the pulsation timescales. Yet most theoretical investigations have assumed that the convective flux is frozen in during the pulsations. This difficult problem is currently being studied.

One very interesting prospect is to try to identify frequencies that are very stable in both period and amplitude to try to measure evolutionary period changes by monitoring the rate of change of the phases of the pulsation. If this can be done, as seems possible so far in the DAV stars (which have been studied for nearly twice as long), we can measure the evolutionary timescales in these stars and calibrate the white dwarf cooling calculations necessary for using the white dwarf stars as galactic chronometers.

Perhaps the greatest mystery of the DB white dwarf stars is their origin. How is a DB white dwarf progenitor different from one that will produce a DA white dwarf? This is especially puzzling given that the mean masses of the DA and DB stars seem to be about the same. Further, along the white dwarf cooling track, the He-rich objects disappear around 40 000 K and do not reappear until just above the temperature of the DBV stars near 30 000 K. Understanding of these evolutionary questions will be dramatically improved if we have accurate measures of the surface layer mass for a significant number of DB white dwarfs, as well as the He-layer mass in the DA white dwarf stars.

The tantalizing results for GD 358 illustrate the potential of asteroseismology for measuring the surface He-layer mass, but they also raise a puzzling question: why is the mass so thin? Standard evolutionary theory suggests the logarithm of the fractional layer mass should be closer to -2 or -3. One possible explanation is that the observed value is not a measure of the actual total He mass but the diffusion boundary as the He percolates up from below. It is also possible that this boundary is not the base of the He layer, but rather the boundary between the relatively lighter ^{3}He and the heavier ^{4}He. If this is the case, then the total layer mass may be approximately the value expected from evolutionary theory. The intriguing possibility of this isotopic separation may have other astrophysical consequences as well. Perhaps it is possible that GD 358 is not typical of the other DB stars for some reason. Only extensive WET-style observations of more DBV stars will tell.

de Chéseaux, Philippe Loys (1718–51)

Swiss astronomer, observed several clusters and 'nebulous stars', and compiled a catalog of their positions, giving it to Reaumur, who presented it to the Académie des Sciences in 1746, but it was not otherwise published. Eight of the nebulae were original discoveries. De Chéseaux was the first to formulate OLBERS' paradox, applied to the Milky Way. If the stars extended indefinitely in all directions every sight-line would end on a star's surface and the Milky Way should be as bright as the surface of the Sun. De Chéseaux suggested that since this was not so there was some sort of attenuation in space, dimming the more distant stars.

de Sitter, Willem (1872–1934)

Cosmologist, born in Sneek, Netherlands, and started a rather traditional career in astronomy, observing with DAVID GILL at the Cape of Good Hope, determining the masses and orbits of the satellites of Jupiter, determining the variation of the rotation of the Earth, and studying the distribution and motions of stars. He became director of the Leiden Observatory, and turned to a range of problems in the theory of relativity. One fundamental tenet of special relativity is the constancy of the velocity of light, and in particular that c. does not depend on the velocity of its source. By analysing the velocity curves of binary star systems, de Sitter proved this. De Sitter created a mathematical theory of general relativity based on four-dimensional space-time and looked at the theory's astronomical consequences. His work inspired ARTHUR STANLEY EDDINGTON'S expedition to measure the gravitational deflection of light rays passing near the Sun during the eclipse of 1919. De Sitter created a general relativistic theory of the Universe, and found solutions that describe an empty Universe, contrary to the principle formulated by ERNST MACH. The solutions that he found described an expanding universe, a theoretical result spectacularly confirmed by EDWIN HUBBLE's observations of the recession of galaxies. De Sitter worked with EINSTEIN on the *Einstein–de Sitter* model of the universe that is the simple basis for current more complex Big Bang models.

Deceleration Parameter

A quantity, denoted by the symbol q, that describes the rate at which the expansion of the universe is slowing down. The value of the deceleration parameter at the present epoch in the history of the universe is denoted by q_0.

Different values, or ranges of values, of q_0 correspond to different cosmological models. For example, if q_0 is greater than $\frac{1}{2}$ the universe is closed and will eventually collapse, whereas if q_0 is less than $\frac{1}{2}$, the universe is open, and will expand forever at a finite rate. The 'flat', or Einstein–de Sitter, universe corresponds to $q_0 = \frac{1}{2}$. The case $q_0 = 0$ corresponds to a universe that expands at a constant rate. A negative value of q_0 corresponds to a universe in which the expansion is accelerating.

In principle, it should be possible to determine the value of q_0 observationally. For example, for a population of uniformly luminous sources (for example, a set of identical supernovae within remote galaxies) the relationship between apparent brightness and redshift is dependent on the value of the deceleration parameter. Although measurements of this kind are notoriously difficult to make and to interpret, recent observations tend to favor q_0 values of less than $\frac{1}{2}$ and hence favor open universe models.

Declination

The angular distance of a celestial body north or south of the celestial equator. In other words, the angle between the celestial equator and a star, measured in a direction perpendicular to the celestial equator. Declination may take values between 0 and 90°, and is taken to be positive for an object north of the celestial equator, and negative for an object south of the celestial equator. Declination is often abbreviated to dec, or denoted by δ. The position of a star is normally expressed in terms of right ascension and declination.

Deep Space (Space Technology)

Series of NASA technology demonstration missions under NASA's New Millennium programme. DEEP SPACE 1 (launched October 1998) carries 12 advanced technologies, including autonomous navigation and ion propulsion. It may be directed to encounter near-Earth asteroid 1992 KD and two comets. Deep Space 2 (launched January 1999) comprises two small surface penetrators, part of the failed Mars Polar Lander mission. Deep Space 3/Space Technology 3 will comprise two spacecraft for testing space interferometry. Launch is scheduled for 2003. Deep Space 4 was cancelled in June 1999.

Breaking news update (30 April 2002)

NASA's Deep Space 1 mission, which successfully tested 12 advanced space technologies and captured excellent images of a comet, came to an end on December 18, 2001. Engineers sent a final command turning off the ion engine, which has used up 90% of its xenon fuel. The spacecraft will remain in orbit around the Sun, operating on its own. Its radio receiver will be left turned on, in case future generations want to contact the spacecraft.

Deep Space 1

Deep Space 1 (DS1) was launched in October 1998 as part of NASA's New Millennium Program and completed its primary mission testing ion propulsion and 11 other advanced, high-risk technologies in September 1999. The DS1 spacecraft flew past asteroid (9969) Braille at a distance of 26 km in July 1999. The asteroid is elongated and irregularly shaped, with a longest side estimated at 2.2 km and its shortest side 1 km. The spacecraft's infrared spectrometer confirmed that the small asteroid is similar to Vesta. It may be ejecta from an impact on Vesta or a sibling with common origin.

NASA extended the mission, taking advantage of the ion propulsion and other systems to undertake an encounter with Comet 19P/Borrelly. The comet was discovered in 1904 by Alphonse Borelly and has a 7 year period. The spacecraft's closest approach to Comet Borrelly in September 2001 was at a distance of only 2200 km (1400 mi). The encounter provided high (100 m) resolution pictures of the comet, sending back black-and-white photographs of the inner core of the 10 km long (more than 6 mi long) nucleus. The pictures showed smooth, rolling plains with brighter regions which seem to be the source of dust jets seen in the comet's coma. Rugged land was found at both ends of the comet's nucleus with many high ridges. This rough terrain contains very dark patches that appear to be elevated compared with surrounding areas.

DS1 also measured the types of gases and infrared waves around the comet and how the gases interacted with the solar wind. A very strong interaction occurs between the solar wind and the comet's coma. Near DS1's closest approach to the nucleus, the solar wind picked up charged water molecules from the coma, slowing the wind sharply. The data show that the flow of ions around the comet's rocky, icy nucleus is not centered on the comet's nucleus. Ions in the turbulent flow are heated to about 106 K (2×10^6 ºF).

Breaking news update (30 April 2002)

NASA's Deep Space 1 mission, which successfully tested 12 advanced space technologies and captured excellent images of a comet, came to an end on December 18, 2001. Engineers sent a final command turning off the ion engine, which has used up 90% of its xenon fuel. The spacecraft will remain in orbit around the Sun, operating on its own. Its radio receiver will be left turned on, in case future generations want to contact the spacecraft.

Degenerate Matter

Highly compressed matter in which the normal atomic structure has broken down and which, because of quantum-mechanical effects, exerts a pressure that is independent of temperature.

At the very high temperatures and pressures that exist inside stars, matter is almost completely ionized and forms a gas of nuclei and electrons (a plasma). When a star has consumed all its nuclear fuel, it shrinks under the action of its own gravity to form, in most cases, a compact white dwarf. As the star shrinks, and its constituent electrons are forced closer together, the volume of space available to each electron rapidly decreases. The Pauli exclusion principle implies that no more than two electrons (electrons with opposite spin) can have the same position and momentum within the limits imposed by the Heisenberg uncertainty principle. As the electrons are pushed closer together, and their separations in position decrease, the differences in their momenta increase, so generating a pressure that, unlike the pressure in a conventional (ideal) gas, depends only on the density of the gas, not on its temperature. Matter in this state is said to be electron-degenerate, and the pressure exerted by the electrons is called electron-degeneracy pressure. Electron-degenerate matter has densities of around 10^6 kg m^{-3}. At very much higher densities, a similar phenomenon, called baryon degeneracy, occurs for protons or neutrons.

Provided its mass is not too great, electron degeneracy pressure prevents a white dwarf from contracting further under its own gravity. If the mass of a collapsed star exceeds about 1.4 solar masses (the Chandrasekhar limit), gravity will overwhelm electron degeneracy and further collapse will ensue. During the ongoing collapse, electrons combine with protons to form neutrons, so producing a neutron star. Because neutrons, too, are subject to the Pauli exclusion principle, at high enough densities (around 4×10^{-17} kg m^{-3}) they form a neutron-degenerate gas that prevents further collapse of the star. The maximum inert mass that can be supported by baryon degeneracy pressure is given by the Oppenheimer–Volkov limit, a limit that is not precisely known but which is thought to be in the region of two to three solar masses. This gives an upper limit for the mass of a neutron star. If a collapsing star exceeds this mass it will form a black hole.

Delambre, Jean Baptiste Joseph (1749–1822)

Astronomer, born in Amiens, France. Produced tables of the location of planets and their satellites from observations made at his private observatory. Succeeded Méchain on the project to determine the size of the Earth, measuring the section from Dunkirk to Rodez. The detailed account of this project forms a three-volume book, and became the base of the metric system, defining the meter. Delambre himself made calculations of the orbit of Uranus, and in his later years wrote a monumental *History of Astronomy*.

Delaunay, Charles Eugene (1816–72)

Celestial mechanician, born in Lusigny-sur-Barse, France, died at sea (near Cherbourg) after just two years as director of the Paris Observatory. Studied lunar theory and worked out formulae that gave the longitude, latitude and parallax of the Moon as infinite series. The work was accurate but impractical as the series converged slowly.

Delisle, Joseph-Nicolas (*fl.* eighteenth century)

French astronomer, member of the Académie, hired CHARLES MESSIER as a draftsman, and as a recorder of astronomical observations. Visited ISAAC NEWTON in London in 1724. Calculated the return path for HALLEY's Comet in 1758–9 and published a map which guided the recovery search, showing the predicted path of return calculated at 10 day intervals. Messier, as his observing assistant, was set to observe the appropriate sectors, and succeeded as the first professional astronomer to see Halley's Comet on its return on 21 January 1759. He had, however, been preceded on Christmas night, 1758, by a German farmer named Palitzsch living near Dresden. Delisle retired and Messier succeeded him as Astronomer of the Navy.

Delphinus

(the Dolphin; abbrev. Del, gen. Delphini; area 189 sq. deg.) A northern constellation which lies between Pegasus and Aquila, and culminates at midnight in late July. It represents either the messenger that the god Poseidon in Greek mythology sent to fetch the sea nymph Amphitrite to be his bride, or the dolphin that was said to have rescued Arion, a semilegendary poet and musician of Lesbos, who had thrown himself into the sea when threatened during a voyage to Corinth. The brightest stars of Delphinus were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A small but conspicuous constellation, the brightest stars in Delphinus are β Delphini (Rotanev), a close binary, integrated magnitude 3.6, with components of magnitudes 4.0 and 4.9, separation 0.2″, α Delphini (Sualocin), magnitude 3.8, and ε Delphini, magnitude 4.0. Interesting objects include γ Delphini, another binary, with orange (K1) and bluish-white (A2) components, magnitudes 4.3 and 5.2, separation 9.8″, and NGC 7006, an eleventh-magnitude globular cluster which, at a distance of about 115 light-years, is one of the most remote.

Delta Aquarids

A meteor shower that takes place in late July and early August. There are two radiants in the constellation Aquarius, one at dec. -17° coming to maximum on 29 July, and the other, slightly weaker, at dec. -10° and coming to maximum around 6 August. The parent body of this shower is unknown.

Delta Cephei

A variable star discovered in 1784 by John Goodricke (1764–86), a young deaf-mute astronomer from York who two years previously had explained the variability of Algol. The first discovered of an important class of variable stars which are now known as Cepheid variables, δ Cephei and other Cepheids of relatively long period now form the subclass 'classical Cepheids'. Cepheids are characterized by the regularity of their periods and the form of their light-curves, and provide a means of measuring distances by the application of the period–luminosity relation. This is especially valuable in the case of those Cepheids found in other galaxies.

The apparent magnitude of α Cephei varies between 3.48 and 4.37 in a period of 5.36634 days; the light curve showing a rise from minimum to maximum in about 1.8 days, followed by a much slower fade to minimum in 3.6 days. The spectral type is G2Ib. It is in fact a multiple star system, having two close companion stars of sixth and thirteenth magnitude. With a parallax of 0.003", the system is 980 light-years distant and is very luminous (absolute magnitude -3.32).

Observations of classical Cepheids begun in the 1890s revealed that their surface temperatures and radial velocities also vary, exactly in phase with their brightness; this indicates that they are actually expanding and contracting in diameter. This pulsation gives rise to the observed variations in temperature and luminosity.

Democritus of Abdera (*c*. 470–*c*. 380 BC)

Philosopher, born in Abdera, Thrace, Greece. Wrote many mathematical works, of which none survive. Suggested that the Milky Way was made up of crowded individual stars. Best known as an atomist philosopher, he claimed that the universe was a mechanical system obeying fixed laws, explaining its origin through atoms moving randomly and colliding to form larger bodies and worlds. In many ways Democritus was the first modern scientist.

Deneb

The star α Cygni, 'the Tail of the Swan'. One of the three bright stars which form the asterism of the Summer Triangle, with Altair and Vega. It is a white supergiant of spectral type A2Ia, apparent magnitude 1.25. It is a very distant star (approx. 3230 light-years, parallax 0.001″), and is the type-star of a class of pulsating variables, varying rather erratically over a range of ± 0.04 magnitudes. It is very luminous, its absolute magnitude being about -8.7.

Denning, William Frederick (1848–1931)

Possibly a journalist and certainly an amateur astronomer. Born in Redpost, Somerset, England. The spectacular meteor storm of 1866, and a fireball in 1869, focused his interest on meteor astronomy. In 1877 he demonstrated a steady night by night movement in the Perseid meteor radiant, which proved that meteors came from showers of dust distributed along the path of a comet. Had the distinction to be cited in H G Wells' *The War of the Worlds* (published 1898): 'Then came the night of the first falling star. It was seen early in the morning rushing over Winchester eastward, a line of flame, high in the atmosphere. Hundreds must have seen it, and described it as leaving a greenish streak behind it that glowed for some seconds. Denning, our greatest authority on meteorites stated that the height of its first appearance was about ninety or one hundred miles.' Published the *General Catalogue of the Radiant Points of Meteoric Showers and of Fireballs and Shooting Stars Observed at More Than One Station*, discovered several comets and Nova Cygni 1920.

Density

The amount of mass contained within a unit volume of material. The mean density of an astronomical body, such as a star or a planet, is simply equal to its mass divided by its volume. In practice, however, the density of such a body increases towards the center. Thus, for example, the density of the surface rocks on the Earth is about half the mean density, while the central density is about 2.5 times the mean value. Astronomical bodies exhibit a wide range of densities. Examples are given below, taking the density of water (1000 kg per cubic meter) as unity.

Object	Mean density (water = 1)	Mean density (kg m^{-3})
Neutron star (typical)	4×10^{14}	4×10^{17}
White dwarf (typical)	10^6	10^9
Earth	5.5	5.5×10^3
Jupiter	1.3	1.3×10^3
Sun	1.4	1.4×10^3
Red giant (typical)	10^{-4}	10^{-1}
Red supergiant (typical)	10^{-7}	10^{-4}
Interstellar gas cloud	10^{-22}	10^{-19}

See also: atmospheric pressure.

Descartes, René (1596–1650)

Mathematician and philosopher, born in La Haye (now Descartes), Touraine, France, settled in Holland. His work, *La Géométrie*, formulated geometry in terms of algebra, from which comes the concept of *Cartesian coordinates*. Studied Aristotelian philosophy and was attracted to mathematics, and the purely logical analysis of practically everything. Wrote *Discours de la Méthode pour bien Conduire sa Raison et Chercher la Vérité dans les Sciences*, expressing optics, the weather and geometry in terms of mathematics. Wrote *Principia Philosophiae* and attempted to put the whole universe on a mathematical basis. Since he did not believe in action at a distance, he assumes that the universe is filled with matter that constitutes a system of vortices which carry the Sun, the stars, the planets and comets in their paths, which for unexplained reasons are ellipses. Despite the problems with the vortex theory it was championed in France for nearly 100 even after NEWTON showed it was impossible as a dynamical system, and it remains a boast in France about one's logical prowess to call oneself a Cartesian.

Detection of Faint Objects

In order to detect a faint object against the sky background, the object must have a signal level in contiguous pixels that is above a set threshold. Thus, the detection limit is set by a limiting isophotal threshold and a minimum object area. The area is typically that of the SEEING disk, i.e. the area of a stellar image. The limiting isophote is typically 2 times the background fluctuations of single pixels. These parameters can be optimized by attempting to detect negative images, which will be entirely due to noise, and then adjusting the minimum area and limiting isophote until the number of noise images is reduced to an acceptable number.

Sky background

The determination of the sky background relies on the assumption that most of pixels in the image are measurements of the sky level, which varies only slowly across the image. The usual procedure is to subdivide the image into tiles, determine the value of the sky background in each tile and then smoothly interpolate the background value at each pixel in the image. The limiting isophote is referenced to this smooth background.

The size chosen for the tiles is a compromise between using small tiles to follow the sky variations and using large tiles to ensure that most of the pixels in any tile are sky, not image, pixels. The sky intensity assigned to each tile should be the intensity value which occurs most frequently in that tile.

Taking the average value of all the pixels in the tile would bias the background too high because of the high values of image pixels that would be included in the average. A much better estimate of the sky background than the average value is the median value obtained by sorting the pixels by intensity values and taking the intensity value from the pixel half way between the first and last after sorting. Typically the median value is used, although more computationally expensive methods for estimating the modal value, the intensity value which occurs most frequently, are sometimes used. These involve smoothing a histogram of pixel values and taking the intensity value corresponding to the peak of the smoothed histogram. The smoothing should be done by convolving the histogram with a Gaussian that has a width similar to that of the histogram. Using the peak of the unsmoothed histogram is too unstable. The histogram must resolve the distribution of intensities around the histogram peak.

Signal-to-noise ratio

The accuracy of the flux measurement of an individual detection is given quantitatively by the signal-to-noise ratio, R. The fractional error is $1/R$. Let S be the detected PHOTON rate in counts per second from the object. The signal, s, is the number of photons detected in the integration time, t; thus $s = St$. The noise, n, is the fluctuation in the number of detected photons, estimated from Poisson statistics as $n = s^{1/2}$. Thus $R = s/n = (St)^{1/2}$ for the case where the only noise source is the signal itself.

Modern astronomical images are obtained with CCD CAMERAS which have readout noise, N, equivalent to a noise signal N^2, associated with each pixel. Additional noise sources are the noise from the sky background in counts s^{-1}/pixel, B, and the dark current in counts s^{-1}/pixel, D. If a is the number of pixels covered by the image, the total noise in the image is that from the sum of the source, the background, the dark current and readout noise,

$$n = (St + Bta + Dta + N^2a)^{1/2} \tag{1}$$

and the signal-to-noise ratio is given by

$$R = \frac{St}{n} = \left[\frac{St}{1 + a(B + D)/S + N^2a/St}\right]^{1/2}. \tag{2}$$

Thus, the integration time, t, required to obtain a given signal-to-noise ratio, R, is

$$t = \frac{R^2}{2S}\left\{1 + a\frac{B + D}{S} + \left[\left(1 + a\frac{B + D}{S}\right)^2 + \frac{4N^2a^2}{R^2}\right]^{1/2}\right\}. \tag{3}$$

For example, consider the integration time required to detect a 22.0 magnitude galaxy in the V band, at a signal-to-noise ratio of 10, with a 48 in telescope using a thermoelectrically cooled back-illuminated CCD detector when the Moon is 7 days old. Assume that the pixel size is 1.1 arcsec × 1.1 arcsec, the galaxy image will be spread over 4 pixels and the cooler operates at −35 °C.

Table 1. Sky brightness.

Lunar age (days)	U	B	V	R	I
	(mag arcsec^{-2})				
0	22.0	22.7	21.8	20.9	19.9
3	21.5	22.4	21.7	20.8	19.9
7	19.9	21.6	21.4	20.6	19.7
10	18.5	20.7	20.7	20.3	19.5
14	17.0	19.5	20.0	19.9	19.2

Table 1 gives approximate sky brightness in various wavelength bands as a function of the age of the Moon. The sky background in the V band from a 7 day old Moon has a surface brightness of about 21.4 magnitudes arcsec^{-2}. The area of a galaxy covering 4 pixels is $a = 4 \times 1.1 \times 1.1 = 4.84$ arcsec^2. Table 2 gives the response of the CCD in terms of detected photons per second from a 20.0 magnitude star observed with a 1 m (39.4 in) telescope and the readout noise per pixel. From table 2, we have $N = 7$ counts/pixel. For a 48 in telescope, the number of counts per second in table 2 must be increased by a factor of $(48/39.4)^2 = 1.48$. The signal from a $V = 22.0$ galaxy is given by $S = 1.48 \times 23 \times 10^{-0.4(22.0-20.0)} = 5.39$ counts s^{-1}, and the sky background is given by $aB = 4.84 \times 1.48 \times 23 \times 10^{-0.4(21.4-20.0)} = 45.8$ counts s^{-1}.

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Table 2. CCD response.

Read noise (counts/pixel)	U	B	V	R	I
		(counts s^{-1})			
7	3.5	20	23	26	12

Table 3 gives the number of dark counts per pixel per second as a function of temperature for a thinned CCD operated in MPP mode, typically devices with 46.0 pA cm^{-2} at 293 K. For a cooler operated at −35 °C, and a galaxy covering 4 pixels, $aD = 4 \times 2.14 = 8.56$ counts s^{-1}.

Table 3. Dark noise.

Temperature (°C)	Dark (counts s^{-1}/pixel)
−30	4.17
−35	2.14
−40	1.18
−45	0.58
−50	0.27
−55	0.13

Substituting the values into equation (3) gives $t = 209$ s to obtain a signal-to-noise ratio of $R = 10$ for a $V = 22.0$ magnitude galaxy.

Detectors: Photography

Photography has had a long and productive partnership with astronomy that is now drawing to a close. Although practical photography appeared in 1837, and solar photography was well established in the 1860s, it was to be almost 50 yr before the technology had advanced enough to be seriously applied to imaging the night sky. After the first demonstrations of its value as a detector of the unseen in 1882–3, by 1890 it had largely displaced the human eye as the main astronomical detector, certainly for objects beyond the solar system. This advance made possible the new science of astrophysics. By 1900 photography had revolutionized the way astronomy was done and within 30 yr had completely changed the perception of our place in the universe. It also profoundly influenced the design of astronomical telescopes and instruments.

It was not until the late 1870s that the long exposures necessary for deep astronomical photography became possible. Before that, photographic emulsions were either too insensitive to be useful or (in the case of wet collodion emulsions) dried out and became insensitive during the necessarily long exposure. The introduction of the 'dry gelatine' process changed that and, for the first time, photographic materials could be prepared well in advance of exposure. Processing could be similarly delayed, and the invention of the dry plate spawned an industry that removed the mystique and practical difficulty from the photographic process, making it widely available. It was in this context that it was found that long-exposure photography could reveal stars that were invisible to the human eye when applied to the same telescope. By 1890, photography was revealing an unseen universe of faint stars, nebulae and galaxies that allowed the burgeoning science of astrophysics to flourish.

Photography as an astronomical detector

In astronomy, photography combines the quite different roles of detector and recording medium. As a detector it remains useful because of its almost unlimited sensitive area, high resolution and signal to noise, excellent uniformity, ready availability and low cost. It is also a very efficient, stable and compact recording medium, with the advantage that the images can be examined easily with a simple light table. However, the detector is non-linear recorder, nor are the analogue records are easily searched, rendered quantitative or duplicated, and it is not easy to make the detector itself into a quantitative tool. Although now largely displaced by electronic image detection, photography still has an important role in modern astronomy, especially in survey and patrol work and in the detection of faint light from extended objects.

The light-sensitive layer of all common photographic materials is a thin coating of gelatine on a suitable substrate, usually glass or transparent film in the case of negatives, paper or plastic for prints. Dispersed throughout the gelatine are minute crystals of silver halides, usually silver bromide or bromo-iodide for the emulsion types used in astronomy. These may be treated with dyestuffs during manufacture to extend the native blue–UV sensitivity of the silver salts to longer wavelengths or to enhance sensitivity to specific parts of the spectrum, such as the 656 nm hydrogen alpha line. Emulsions with useful (although low) sensitivity to wavelengths as long as 1.2 μm have been made.

Astronomical photography is a very challenging situation for the photochemist. Because light levels are usually very low, the emulsion must be highly sensitive. However, if good sensitivity is achieved, the ever-present glow of the night sky masks the signals from faint celestial sources. The primary aim in the early days of astronomical photography was to have a detector as sensitive to faint light as possible, in other words, with a high quantum efficiency.

This property was of interest to the commercial manufacturer as well as the astronomer, and astronomers were fortunate that C E Kenneth Mees, founding director of the Eastman Kodak research laboratories, had an interest in astronomy. This led to the introduction of the extremely sensitive Kodak 'Spectroscopic Plates' in the 1930s. These were materials designed to have high sensitivity to faint light, where exposure times were necessarily long. They were used for recording astronomical spectra as well as the direct imaging of faint light. Although it was eventually realized that these tasks were often quite different image recording problems, these fast, coarse-grained, low-resolution products were widely used in the astronomical community until about 1990.

Although low resolution and high granularity were not too important with long-focus telescopes with large plate scales, it was not the ideal combination for recording faint, finely structured spectra in the absence of non-image background light, nor for recording any kind of image where the object of interest was fainter than natural night sky airglow. The introduction of fast, Schmidt-type telescopes in the 1930s, with their finely detailed images and small image scales, served to emphasize the poor imaging properties of the early materials. Eventually (in the late 1960s) the fast, grainy materials were displaced by new products designed for faint object detection, not high speed. It was gradually realized that the important factor in image detection was detective quantum efficiency (DQE), rather than simple quantum efficiency:

$$\mathrm{DQE} = \frac{(S/N)^2_{\mathrm{out}}}{(S/N)^2_{\mathrm{in}}}.$$

DQE is usually expressed as a percentage, where

$$(S/N)_{\mathrm{out}} = \frac{\log_{10} \mathrm{e}\, \gamma}{\sigma_{\mathrm{D}}}$$

where γ is the contrast, or slope of the characteristic (H&D) curve of the photographic material at the sky background density, and σ_{D} is the rms diffuse density noise. Considered in this way, the older, highly sensitive

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

emulsion types (e.g. Kodak Type 103a) had a DQE of about 0.1% at best, while the Kodak IIIa types that replaced them have DQEs of 3–5%. A more recent development, Eastman Kodak's Tech Pan, has an even higher DQE.

The result of these considerations was for the manufacturers to make the emulsions more contrasty (to discriminate faint signals in noise) and finer grained (to improve the signal statistics). However, although finer grains give greatly improved imaging properties, they always yielded less sensitive emulsions. This nexus was broken in the early 1970s, when it was found that baking emulsions just before exposure gave much improved long-exposure performance, mainly by eliminating low-intensity reciprocity failure (LIRF). LIRF was reflection of the electronic inefficiencies in the light detection process which are important at the low photon arrival rates found in astronomy. The processes that counter these inefficiencies are generally known as 'hypersensitization' (hypering). They do little to improve the 'snapshot' or short-exposure sensitivity of the products concerned, but can improve the sensitivity for exposures of many minutes by a factor of 30 in some cases.

Further advances, especially the use of hydrogen as a reduction sensitizer in 1974, and the exposure at the telescope of the hypersensitized material in an inert atmosphere, have enabled extremely fine-grain materials to be used on all telescopes with exposure times comparable with the earlier generation of coarse-grained emulsions. The fine-grained emulsions and use of hydrogen originated in the Eastman Kodak research laboratories, but many astronomical practitioners became skilled at the complex hypering processes, often gas treatments that made the use of the new materials a practical possibility. They also developed their own variations of these processes, skills that have been of particularly important with Schmidt-type instruments specializing in survey work.

Practical considerations

The high-contrast nature of modern photographic emulsions has made them much more difficult to handle, a problem compounded by hypering. In general, high contrast implies that the exposure latitude is very limited. Moreover, it was soon found that the level of exposure was much more critical with the contrasty emulsions than with their relatively low-contrast forebears. The ideal situation was to adjust the exposure so that the density produced by the night sky AIRGLOW was at a developed density of about 1.0 above the chemical fog of the plate. This ensured that the minimum density on the plate was close to the maximum contrast of the emulsion, thus maximizing output signal to noise. However, this implied adjusting the effective exposure within a range of about 10%, a much tighter tolerance than is usual in photography. This in turn implied a knowledge of the (variable) night sky brightness and of the effective sensitivity of the material, which had been greatly increased by hypering. The influence of these variables is reduced by regular measurement of the night sky brightness and an extensive program of testing the effects of hypersensitizing.

A further difficulty with high-contrast emulsions was their extreme sensitivity to processing variations and to mishandling, especially after hypering. The overall effect of the newer emulsions was to force rapid improvements in photographic technique that are reflected in the quality of the recently completed sky surveys and which also positively benefited the last few years of photographic observing on large reflectors.

Photography as a recording medium

It is with Schmidt telescopes that the large sensitive area and high spatial resolution of modern photographic emulsions are best utilized, and it is no accident that Schmidt telescopes are still the main users of photography today. These instruments have fast focal ratios, typically between $F/1$ and $F/3$ and cover wide angles of sky, often many degrees across. Their continued use of photography is not conservatism; rather it is a recognition that the high information content of the wide-field images captured by these telescopes is most efficiently recorded with modern, hypersensitized photographic emulsions. In addition, the world's observatories have substantial photographic archives from larger telescopes and these are a valuable resource.

The UK Schmidt Telescope at Siding Spring in Australia and its northern counterpart, the Oschin Schmidt at Mt Palomar in California, have focal planes measuring 356 mm square, covering $6.6^\circ \times 6.6^\circ$ of sky (see MOUNT STROMLO AND SIDING SPRING OBSERVATORIES, PALOMAR OBSERVATORY). Equipped with hypersensitized Tech Pan film they have a detector with effectively 5 μm pixels operating at a DQE of much better than 5%. Although this is an order of magnitude less sensitive than a CHARGE-COUPLED DEVICE (CCD), CCDs are still limited to much smaller fields and pixels that are effectively 2 or 3 times larger, so the total observing efficiency can still be higher with photography. This has not prevented the very effective use of CCDs in Schmidt telescopes.

Although the basic solid-state mechanisms of photodetection in CCDs and photographic plates are similar, there the similarity ends. After exposure, the latent images on photographic plates and film are developed by immersing the material in a sea of electrons, a chemical reducing agent (developer) that amplifies the photo-electric effect of the photons by a factor of a billion or so. After the removal of the unexposed silver halide ('fixation') the final result is matrix of metallic silver particles suspended in a thin, clear gelatine layer. This is the photographic negative, and in many applications this is the final photographic stage. However, this negative can be copied to produce large numbers of identical-looking duplicates, or portions of it can be photographically enhanced in various ways to extract otherwise hidden information. The large fields are also useful for making color images of the sky.

Much more often nowadays, the original negatives are digitized with specialized scanning machines to

Dirac House, Temple Back, Bristol, BS1 6BE, UK

convert the 10^5–10^6 analogue images buried in the silver grains into digital form. This enables many plates of the same field to be digitally 'stacked', which effectively improves $(S/N)_{\rm out}$ by a factor close to $N^{1/2}$ where N is the number of plates. However, it should be noted that even the most modern current measuring machines such as SuperCOSMOS in Edinburgh, which scans in 10 μm steps, may not be able to extract all the useful information from an exposure which has an inherent resolution around 5 μm. Multiple exposures can also be combined photographically to great effect, and photographic imaging methods such as unsharp masking are also still useful with original plates, where the maximum photographic density in well-exposed areas may be well above the density that can be probed by digitizing machines.

Nonetheless, from these databases, accurate positions, parallaxes and and proper motions (transverse angular velocities) for stars can be derived, as well as information about VARIABLE STARS. With extended objects, the position angles and counts of GALAXIES (for example) can be measured and the detection of faint, extremely extended galaxies that are normally undetectable by visual inspection is simplified. More sophisticated manipulations on sets of plates, especially measurements of the color of objects, lead to large catalogues of high-redshift QUASARS and other unusual objects and recently the detection of a large galaxy in the process of merging with the Milky Way.

It seems likely that the high sensitivity and excellent storage capacity of photographic plates will continue to be an economical and convenient way to gather and store data for some time to come, although those data will be increasingly analyzed and disseminated in digital form.

Detectors: Superconducting Tunnel Junction Devices

The absorption of a photon of a wavelength λ (nm) in a superconductor is followed by a series of fast processes which involve the breaking of Cooper pairs by energetic phonons created by the hot electrons produced as the atom relaxes after the initial photoabsorption. The result of this cascade essentially is that the photons' energy is converted into a population of free charge carriers known as quasiparticles in excess of any thermal population. For typical transition metals this conversion process ranges from nanoseconds (niobium) to microseconds (hafnium). At sufficiently low temperatures (typically about an order of magnitude lower than the superconductor's critical temperature T_c) the number density of thermal carriers is very small while the average number of excess carriers N_0 created as a result of the photoabsorption process can be written as

$$N_0(\lambda) \sim 7 \times 10^5/\lambda\ (\mathrm{nm})\Delta(T/T_c).$$

Here the wavelength is expressed in nm and the temperature-dependent energy gap $\Delta(T/T_c)$ is in meV. Thus in a superconductor such as tantalum with $T \ll T_c$ (4.5 K) the initial mean number of free charge carriers created $N_0(\lambda)$ is $\sim 10^3$ eV^{-1}.

The variance on $N_0(\lambda)$ depends on the variance in the partition of the energy of the photons between productive phonons (phonons with an energy $\Omega > 2\Delta$ which can break Cooper pairs) and phonons which are essentially lost from the system ($\Omega < 2\Delta$). The population of $\Omega < 2\Delta$ phonons evolves with time as the average energy of the increasing quasiparticle population relaxes, through quasiparticle phonon emission, towards the bandgap. The variance $\langle N_0 \rangle$ depends on the superconductor's bandgap Δ and its Fano factor F such that

$$\langle N_0 \rangle \sim 7 \times 10^{-4}\mathrm{F}/[\lambda\ (\mathrm{nm})\Delta(T/T_c)].$$

Expressing this variance in terms of the wavelength resolution we have

$$\mathrm{d}\lambda_\mathrm{F}\ (\mathrm{nm}) \sim 2.8 \times 10^{-3}\ \lambda^{3/2}[F\Delta(T/T_c)]^{1/2}.$$

It has been shown that $F \sim 0.2$ for elemental superconductors such as niobium and tin (Kurakado 1982, Rando *et al* 1992). This therefore represents the fundamental Fano limited resolution of any superconductor. Thus a superconductor such as tantalum with $T \ll T_c$ irradiated with photons of wavelengths covering the x-ray to the near infrared $\lambda \sim 1$, 10, 100 and 1000 nm then $\mathrm{d}\lambda_\mathrm{F} \sim 0.001$, 0.033, 1.07 and 34 nm respectively (Peacock *et al* 1997, 1998).

The quasiparticles produced through photoabsorption can be detected by applying a d.c. potential across two such films separated by a thin insulating barrier, forming a superconducting tunnel junction (STJ). This potential bias favors the transfer of quasiparticles from one film to the other through quantum mechanical tunneling across the barrier. The detector signal is therefore represented by the current developed by this tunnel process. After initial tunneling, a quasiparticle can tunnel back, therefore contributing many times to the overall signal (Grey 1978). On average each quasiparticle will contribute $\langle n \rangle$ times to the signal through an average of $\langle n \rangle$ tunnels before it is lost from the system through traps etc (Poelaert *et al* 1999). Hence the mean number of effective charge carriers $N = nN_0$. The multiple tunnel process leading to n the average number of tunnels per quasiparticle is of course subject also to statistical fluctuation (Goldie *et al* 1994). The fluctuations due to the Fano process and that arising from the tunnel process can be added in quadrature such that the overall limiting resolution for a perfectly symmetrical superconducting tunnel junction can be written as

$$\mathrm{d}\lambda_\mathrm{T}\ (\mathrm{nm}) \sim 2.8 \times 10^{-3}\lambda^{3/2}\Delta(T/T_c)^{1/2}(F + 1 + 1/n)^{1/2}$$

for the case when $n \geq 2$. Figure 1 illustrates this tunnel junction limited resolution for a number of elemental superconductors based on the parameters summarized in table 1. Note this expression for the tunnel limited resolution $\mathrm{d}\lambda_\mathrm{T}$ can be further generalized to any superconductor compound or proximized bilayer through the use of the approximate BCS relation in the weak coupling limit of $2\Delta = 3.5kT_c$, where k is Boltzmann's constant. Deviations from this relation are small even for strongly coupled superconductors such as niobium and are also summarized in table 1. Thus in terms of the critical temperature we can write

$$\mathrm{d}\lambda_\mathrm{T}\ (\mathrm{nm}) \sim 1.1 \times 10^{-3}\lambda^{3/2}T_c^{1/2}(F + 1 + 1/n)^{1/2} \quad (n \geq 2).$$

Typically n is of order 10–100 and depends on the size and nature of the STJ.

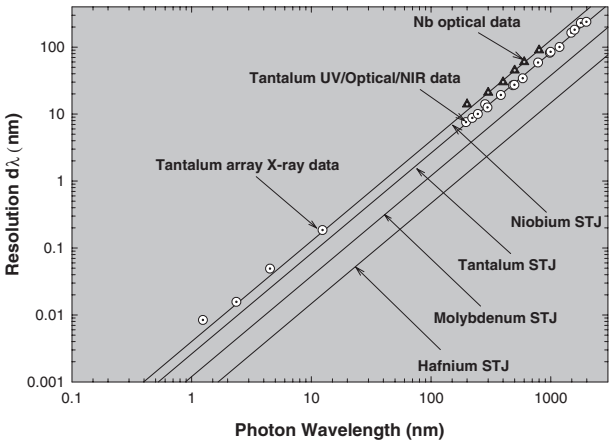

Figure 1. The tunnel limited resolution of a number of elemental superconductors as a function of wavelength from the x-ray to the near infrared. The experimental data derived from niobium and tantalum STJs are also shown.

Astrophysical rationale

Having established the limiting wavelength resolution $d\lambda_T$ of an STJ it is worth considering the applications of such a resolution within such fields as astrophysics.

X-ray wavelengths

Any PLASMA at a temperature above $\sim 10^6$ K radiates the bulk of its energy as x-rays from collisional excitation line emission and thermal bremsstrahlung continuum processes. At low temperatures ($<10^7$ K) the bulk of this photon emission is in the form of emission lines radiated in the soft x-ray band (SXB) with $\lambda > 0.5$ nm ($\sim$2 keV), while at higher temperatures continuum emission processes dominate. This only arises as a result of the fact that at higher temperatures the majority of ions with a low atomic number are completely stripped of their electrons while the remaining ions are hydrogenic or helium-like species of sulphur and iron.

High-resolution x-ray spectroscopy (see X-RAY ASTRONOMY) provides the ability to determine the electron and ion temperatures the electron density and the relative abundance of the elements, as well as establishing the degree of thermal and ionization equilibrium. While the measurement of the intensity of the hydrogenic and helium-like lines from the same element is an important ion temperature indicator, it is the ability to resolve the satellite lines, e.g. the resonance, forbidden and intercombination lines, from helium-like species which can determine the key characteristics of the x-ray emitting plasma in a model independent manner. Table 2 summarizes these key transition wavelengths for some of the most abundant elements expected to be present in an astrophysical plasma together with the tunnel limited resolution of a tantalum based STJ at these wavelengths. Clearly such an STJ, provided it can achieve a measured resolution close to $d\lambda_T$, should be capable of resolving these key transitions. To illustrate this point figure 2 shows the response of a tantalum STJ to the large complex of lines (the Fe-L complex) around 1 nm, expected to be radiated from an optically thin plasma having a temperature $\sim 10^7$ K. In this example SOLAR ABUNDANCES and ionization equilibrium were assumed, and for clarity the continuum emission has been suppressed. The majority of lines are easily resolvable with such a tantalum STJ enabling the temperature to be uniquely determined

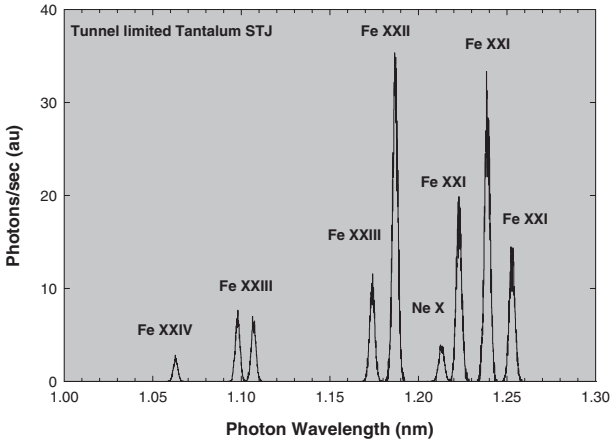

Figure 2. The simulated response of a tantalum based STJ to the Fe-L complex of lines around 1 nm from a hot optically thin plasma at a temperature of 10^7 K. Practically all the lines are resolvable by such a detector.

through the measurement of the relative intensity of the lines from the same ion. Also, through the relative intensity of lines from different elements such as Fe and Ne, the relative abundances can be established. Note that the intensity ratio of resonance lines from different ions of the same element together with line centroids allows one to deduce either the degree of ionization equilibrium or possibly distance to the object, through the determination of the REDSHIFT z. Needless to say, a high spectral resolution is required for such observations. This resolution can be achieved using a tunnel limited tantalum STJ but is completely impossible with conventional solid state devices.

To illustrate the high degree of sensitivity of various emission line strengths to plasma temperature figure 3(a, b) shows the simulated tantalum STJ response to emission line spectra from a hot solar abundant optically thin plasma in equilibrium over the wavelength region covered by the hydrogenic and helium-like oxygen lines $\sim$2 nm. Again for clarity the continuum has been suppressed. The ion temperature T was taken to be $\log T \sim 6.4$ and 6.8 respectively. This temperature can be established directly from the line intensities

Oxygen	2.1602	2.1804	0.0202	2.2100	0.0296	0.0083

R = Resonance line, I = intercombination line and F = forbidden line transition. All line wavelengths are in nm. $d\lambda_T$ (nm) the tantalum tunnel limited STJ resolution determined at the resonance line wavelength.

without recourse to modeling the underlying continuum bremstrahlung spectrum which anyway provides only a measure of the free electron temperature.

UV/optical wavelengths

In optical and UV spectroscopy high resolution normally implies a resolving power $\lambda/d\lambda > 10^4$. From figure 1 it is clear that none of the classical superconductors forming the basis of current STJs under development (those based on Nb, Ta, Al, Mo or Hf) could achieve such a resolving power. In fact a superconducting critical temperature $T_c \ll 100\ \mu$K is implied to achieve a resolving power of 10^4 leading to the development of STJs based on such elemental superconductors as rhodium. Of course things are not quite this simple, with the temporal characteristics associated with the production of the free excess charge carriers being a function of the critical temperature (see table 1) while the phonons with $\Omega > 2\Delta$ have wavelengths significantly larger than the thickness of the film. Thus such low-temperature superconductors may well be significantly slower in their overall in response.

Given that the resolution of a typical STJ based on tantalum is not appropriate for high- or even medium-resolution spectroscopy what are the alternative key attributes which such a device can bring to the fields of OPTICAL/ULTRAVIOLET ASTRONOMY? Two features are important: (a) The timing characteristics ($\leq$10 μs) coupled to the broadband spectral capability may make this the ideal spectrophotometer: objects such as pulsars and flare stars may be ideal objects with which to observe with narrow field small arrays. (b) The efficiency at UV wavelengths which, if coupled to a large format array (a panoramic detector), may allow for the development of an efficient broad band imaging spectrometer with which to determine the low-resolution spectra of very faint objects allowing for very deep field surveys. Such surveys could allow the determination in a single exposure of the broadband spectra and possibly therefore the redshift z (and therefore age) of all objects in the field through the measurement of the Lyman edge and the Lyman emission lines—the Lyman forest. Note that the observed wavelength $\lambda_o = \lambda_R(z+1)$, where λ_R is the rest wavelength. Thus the classical Lyman edge would appear at $\sim$400 nm at $z \sim 3$. This is close to the optimum performance for a tantalum based STJ where it has an efficiency of $\sim$70% and a resolution of $\sim$20 nm. It is, however, clear that STJ devices based on lower-temperature superconductors such as hafnium would allow the clear evaluation of redshift.

Current performance of STJs

The key factors described in this section involve the basic performance of tantalum based STJs building on the earlier work in niobium. The validation of the basic equations discussed earlier relating to both N_0 and $d\lambda_T$ with both tantalum and niobium devices give some confidence in the ultimate successful development of lower-temperature elemental superconducting tunnel junctions such as those based on hafnium (Kraft *et al* 1998).

X-ray wavelengths

The efficiency of any detector is an important parameter when considering practical applications. Figure 4 illustrates the efficiency of a tantalum based STJ as a function of photon wavelength for the case when one film about 100 nm thick is used as the primary detection element. For comparison the efficiency of a hafnium film is also shown. Little difference exists between such films given their similar atomic numbers although their tunnel limited resolution should be very different. At a wavelength of 2 nm the efficiency is $\sim$75%; however, the situation rapidly degrades at shorter wavelengths with an efficiency of only 5% at 0.2 nm. While the thickness of these films can undoubtedly be increased to 200–300 nm, beyond this various loss mechanisms may become important such that the spectral resolution could be expected to degrade. Of course in practice the efficiency at the longer wavelengths will be lower than that indicated in figure 4 due to the fact that unlike in the optical/UV where back illumination is the mode of operation, at x-ray wavelengths the photon enters the detector through the front (front illumination). This means that some fraction of the x-rays at long wavelengths are absorbed in the top film oxide layer and also the top film, if the bottom film is used as the primary detection film, as well as the top contact. This latter point is important when considering arrays in which a significant amount of top contact wiring together with a SiOx insulation layer is required.

While the resolution in the medium x-ray band (MXB $\sim$ 0.1–0.5 nm) has not yet reached the tunnel limits indicated by figure 1, the situation in the soft x-ray band (SXB $\sim$ 0.5–10 nm) is close. Figure 5 illustrates the measured spectra from a tantalum STJ forming part

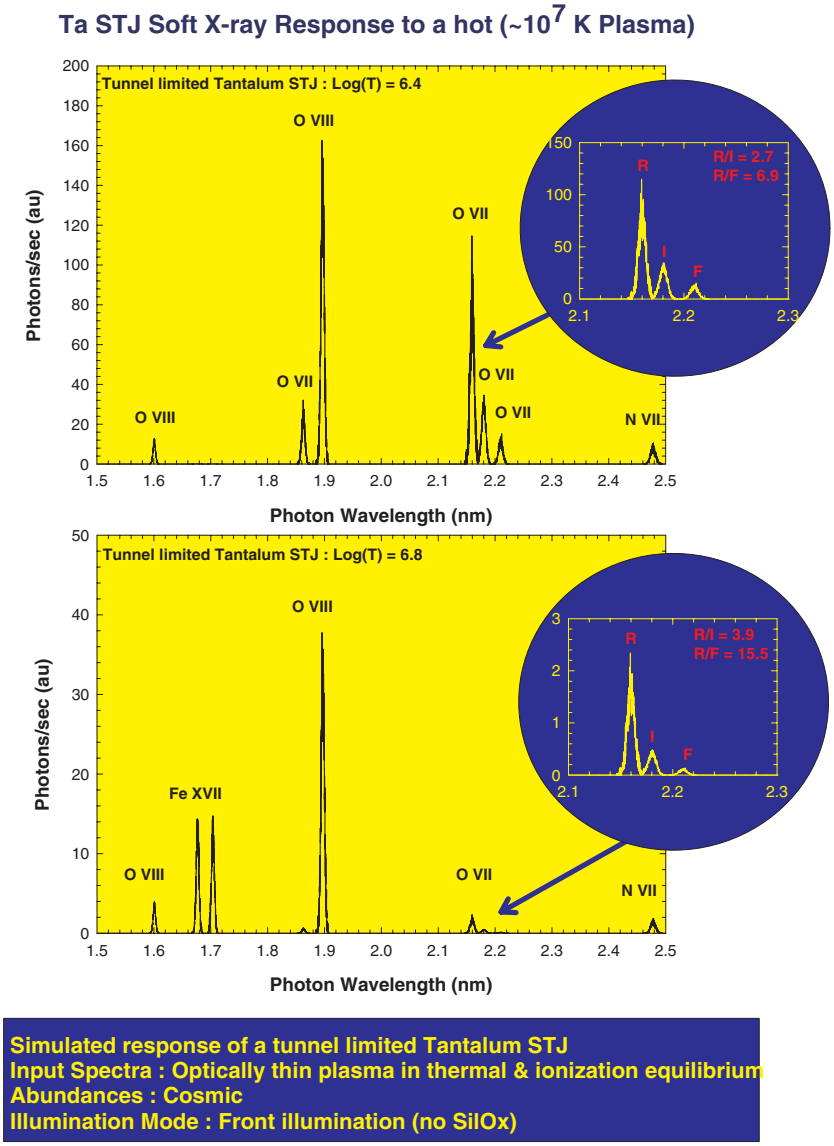

Figure 3. The simulated response of a tantalum based STJ to the helium and hydrogenic lines of oxygen at a temperature T of (*a*) $\log T = 6.4$ and (*b*) $\log T = 6.8$, from an hot optically thin plasma. Note the difference in scale between the two spectra as well as the radically different line ratios when the temperature has changed by only a factor of 2.5.

of a 6 × 6 element array illuminated by monochromatic radiation of various wavelengths in the SXB (Rando *et al* 1998). Each device was 25 × 25 μm and consisted of two films each 100 nm thick. Only those photons absorbed in the base film, which are separated from top film and substrate events by their distinct signal risetime are shown here. Typical resolutions $d\lambda \sim 0.015$ nm (3.5 eV) at $\lambda \sim 2.4$ nm (∼500 eV) were measured and are indicated in figure 1. While these data have not yet achieved the tunnel limited resolution ($d\lambda_T \sim 0.01$ at $\lambda \sim 2.4$ nm) the cause is determined to be a spatial variation in the detector gain which provides an additional variance dependent on the square of the photons energy and which contributes to the overall variance (Verhoeve *et al* 1998).

UV/optical wavelengths

At optical and UV wavelengths, where the photon energy is very small, spatial effects on the resolution are unimportant. Here it is rather that the signal is low such that the signal to noise ratio is the dominant factor governing the measured resolution. At these wavelengths the photons enter the detector through the substrate, which can either be sapphire or magnesium fluoride depending on the short-wavelength cut-off required (Peacock *et al* 1998). The theoretical efficiency of a tantalum device deposited on a sapphire substrate with this mode

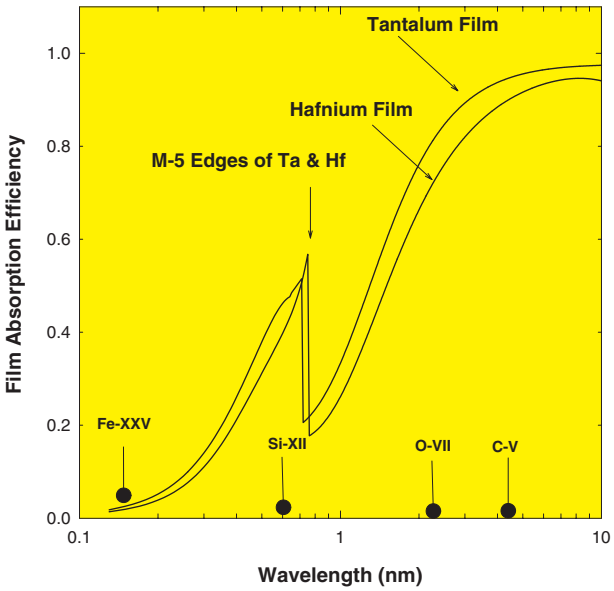

Figure 4. The efficiency of a tantalum and hafnium 100 nm film to the absorption of x-rays as a function of wavelength. Some key emission lines are indicated.

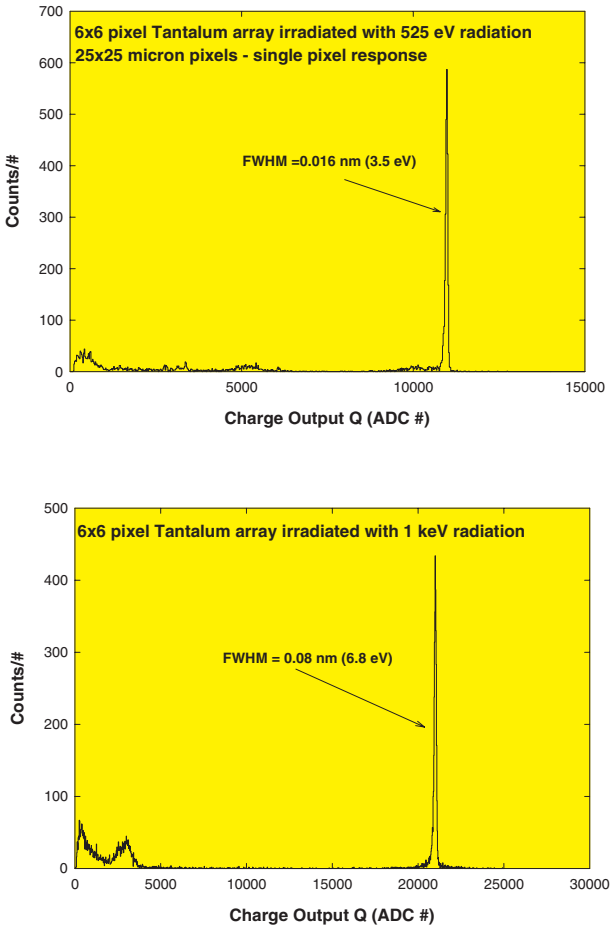

Figure 5. The spectra from a single pixel of a 6 × 6 tantalum array illuminated by monochromatic soft x-rays.

of illumination is very high. All photons are absorbed in the high-quality epitaxial tantalum base film. Efficiencies of ∼70% from 200–600 nm are expected limited at the short wavelength by the cut-off of the sapphire substrate. Such efficiencies have been experimentally confirmed.

To illustrate the broad band response of this type of photon counting spectroscopic detector, figure 6 shows the charge spectrum from a single tantalum based device when illuminated with optical light via a grating monochromator. This grating response covers four orders from 296 nm to 1183 nm, i.e. from the UV to the NIR. Not only are the various orders well resolved but the charge output as a function of wavelength can be precisely determined leading to a wavelength linearity which is very high. These types of measurements allow the determination of the wavelength resolution across a broad waveband and are shown for both tantalum and niobium based devices in figure 1.

Conclusion

The STJ based currently on tantalum or niobium has now been developed to a stage where practical small format arrays (3 × 3 and 6 × 6 pixel) have been produced which provide similar performance to optimized single devices. Such arrays are already being developed into instruments for ground based optical astronomy (Rando *et al*). The performance of these arrays at UV and SXB wavelengths is such that practical instruments can now be considered for space based applications. The key specific points which have been experimentally demonstrated can be summarized as:

(a) Tunnel limited resolutions have been achieved at optical and UV wavelengths.
(b) High efficiency has been shown at UV wavelengths.
(c) Resolutions are within a factor of two of the tunnel resolution in the SXB.
(d) High-speed photon counting has been realized (10 kHz).

Areas where development of the basic tantalum device are still required can be summarized as:

(a) Reduction of the spatial contribution to the resolution allowing for the demonstration of tunnel limited resolution in the MXB.
(b) Improvement in the efficiency of the device in the MXB
(c) Reduction in the various absorbing materials (contacts, SiOx etc) which reduce the efficiency in the SXB.
(d) Production of very large format arrays.
(e) Development of large format application specific readout electronics.

Diamond Ring

An effect observed at the onset and end of the totality phase in a total eclipse of the Sun. Just as the extreme edge of the Sun's disk is about to disappear behind (or emerge from behind) the Moon's disk, a bright arc of sunlight is seen, giving the impression of a ring. In conjunction with Baily's Beads-type bright points, the ring has highlights like a diamond ring.

Dichotomy

The phase of a body in the solar system when exactly half of its sunlit side is visible. The term is used in particular for the half-phases of the inferior planets, Mercury and Venus; in correct usage it is not applied to the Moon, for which the terms first quarter and last quarter are preferred. Other bodies in the solar system can be imaged at dichotomy only by spacecraft.

Dicke, Robert Henry (1916–)

Physicist, born in St Louis, MO, professor at Princeton (1946–84). He did not believe EINSTEIN's general theory of relativity and conducted numerous experiments to challenge its famous tests. He attempted to determine whether the Sun was oblate (squashed at the poles) and could thus cause alterations to the orbit of Mercury which had been interpreted in Einstein's favor. He re-measured the gravitational deflection of starlight by the Sun. He measured the position of the Moon by laser beams reflected back to Earth. He determined the age of the oldest stars. All this was to look for effects that would provide evidence of his own theory. This was all in vain, and his challenge was unsuccessful. He was, however, a believer in the theory that the universe began with a Big Bang, and had identified the possibility that there would be a microwave remnant of that event. He was building a radiotelescope to look for it when ROBERT WILSON and ARNO PENZIAS found it while engaged on other studies. Some claimed that Dicke should have shared in the Nobel prize with them.

Differential Rotation

The variation with latitude of the angular rotation rate of the Sun. From studies of the motion of sunspots across the solar disk, carried out between 1853 and 1861, English astronomer Richard Carrington (1826–75) showed that the angular rotation rate of the solar surface decreases, and the rotation period increases, with increasing latitude north or south of the solar equator. Although sunspots are seldom observed at latitudes much higher than about 30°, measurements of rotation rates at a wide range of latitudes can be obtained by measuring Doppler shifts in the wavelengths of spectral lines at different points on the Sun. Recent observational data indicate that the sidereal rotation period of the photosphere increases from 24.8 days at the solar equator, to 26.1 days at latitude 30°, about 31 days at latitude 60° and approximately 35 days at the poles.

Helioseismology (a technique for studying the structure and motions of the solar interior) indicates that differential rotation extends down to the base of the convective zone, which is located at a depth equal to 29% of the Sun's radius, but that below this level the solar interior has a near uniform rotation period of just under 27 days.

Differentiation

The process by which a planetary body (a solid planet or major satellite) acquires a layered structure with dense materials at its center, in a core, and less dense materials in an overlying mantle and crust. A body that has formed by accretion has a homogeneous composition, with materials of different densities distributed uniformly throughout its volume. In order for its constituent materials to begin separating out, the interior of a body must begin to melt. The heat required for melting comes from a number of sources. They include gravitational compression (temperature increases with pressure, heating the center), the kinetic energy of further impacts (which is converted into heat energy, heating the surface), radiogenic heating (energy is released when radioactive elements decay, heating the whole body) and tidal forces (exerted by a planet on a satellite, deforming it and thus heating the interior). Once a body is at least partially molten, dense materials can start to gravitate toward the center, where they form a core, while less dense materials begin to float toward the surface, where they form a mantle and crust. Differentiation is thus driven by gravity, which also plays a part in the melting that makes it possible, so the process can take place only in bodies that have grown sufficiently large. The temperature at which melting can commence depends on the melting points of a body's constituent materials.

Differentiation of the terrestrial planets typically began with the formation of a *core*. Once molten at the center, dense material (in the Earth's case, predominantly iron and nickel) would quite quickly segregate toward the center. The gravitational potential energy released by core formation would have been converted into enough heat to melt all of the overlying layers, forming a rocky *mantle*. After this initial phase, with the outer layers solidifying as heat was radiated into space, the other factors played a greater part. Radiogenic heating in the mantle produced partial melting, forming pockets of lighter magmas which rose to the surface, erupting as volcanoes, a process which continues on the Earth and, quite possibly, Venus. Impacts, particularly in the period known as late heavy bombardment which ended about 3.9 billion years ago, provided the energy to melt the entire surface, creating global magma oceans in which lighter material formed by chemical segregation floated to the surface (in much the same way as slag forms at the top of a blast furnace), to solidify as a *crust*.

Larger satellites in the outer solar system are also believed to have undergone differentiation. For Jupiter's Galilean satellites, tidal heating may well have been a contributory factor at some stage in their internal evolution. Io, Europa and Ganymede are thought to be fully differentiated, with predominantly iron cores surrounded by silicate mantles (molten in Io's case) and ice crusts, Ganymede having in addition a substantial icy outer mantle. The most distant of the four, Callisto, is thought to have only a partially differentiated rock/ice interior. Mid-sized icy satellites of Saturn and Uranus may well have experienced differentiation, mainly through radiogenic and tidal heating. This would have been possible through the formation of what is known as a eutectic melt of ammonia and water, which is molten at a temperature as low as 176 K, and behaves under the prevailing conditions rather as magma on the Earth. The strange surface of Miranda is thought to have resulted partly from an incomplete differentiation that affected some parts of the surface only.

In the asteroid belt, Vesta is the only body for which there is good evidence for differentation having occurred, and which has survived intact the catastrophic collisions that completely disrupted other differentiated bodies to produce, for example, the M and R class asteroids, and ion meteorites.

Diffraction

The bending and spreading out of waves (for example light waves or water waves) that occurs when they pass by the edge of an opaque object or through a narrow slit or aperture. Light waves from a distant point-like source advance as a series of wavefronts ('crests' and 'troughs') that lie at right angles to the direction in which the light is propagating (like ocean waves rolling up onto a beach). Diffraction occurs because each point on an advancing wavefront acts as a tiny source of wavelets that spread out spherically. When the wavefronts from the source are interrupted, by encountering an opaque obstruction or by passing through a slit or aperture, secondary wavefronts spread out from the edges of the obstruction or aperture. This causes some of the light to pass into what ought (if light rays traveled purely in straight lines) to be the geometric shadow of the object, and causes the edges of shadows cast by opaque objects to be fuzzy rather than perfectly sharp.

When a wavefront is imaged after passing through a slit-shaped aperture, the resulting image consists of a narrow central band of light together with, on either side, a number of successively fainter bands. This pattern, which is called a diffraction pattern, arises from the mutual interference of waves originating at different parts of the aperture. The paths along which these waves have traveled in order to reach the same point differ in length, so the waves arriving at a particular point are out of phase to a greater or lesser extent. Where the path difference is precisely half a wavelength (or an integral number of wavelengths plus half a wavelength) they will be 180 degrees out of phase (a crest from one coinciding with a trough from the other) and will cancel out. Where the path difference is a whole number of wavelengths, they will be in phase (a crest coinciding with a crest) and will add together to produce a crest of larger amplitude. The central brightness maximum occurs where a large number of waves reinforce each other. The first minimum arises where the path difference from opposite sides of the aperture is half a wavelength, so the waves from one side cancel the waves from the other. The next maximum occurs where the path difference is a full wavelength, and so on. When light passes through a circular aperture, the resulting diffraction pattern consists of a central spot (which is called the 'Airy disk'), into which most of the light is concentrated, surrounded by a series of concentric light and dark rings (or 'fringes').

The magnitude of any diffraction effects depends on the wavelength of the light and the size of the aperture (the longer the wavelength, or the smaller the aperture, the larger the diffraction pattern). Diffraction affects the quality and sharpness of images produced by optical systems. In particular, the theoretical resolving power of a telescope is determined by the size of the Airy disk that is produced when a point-like source, such as a star, is imaged.

Diffraction Grating

A plate on which a large number of parallel grooves or slits have been cut and which spreads light into its constituent wavelengths, so producing a spectrum. When a collimated beam of light falls on the grating, light is diffracted by each of the grooves or slits and, in certain particular directions, waves of different wavelengths leaving the different parts of the grating interfere with each other to produce a spectrum. A diffraction grating that transmits light is called a transmission grating and a grating that works by reflecting light from the surfaces of the grooves is called a reflection grating. Most astronomical spectrographs employ reflection gratings.

The resolving power of a grating (its ability to reveal fine detail in a spectrum) depends upon the total number of grooves that it contains. Gratings used for optical astronomical purposes typically have between 100 and 1000 grooves per millimeter and contain between 1000 and 50 000 grooves in all.

A simple grating spreads the incoming light into a large number of spectra, the fraction of the light going into any one spectrum being relatively low. In order to overcome this problem, the reflecting surfaces of the grooves are orientated at a particular angle (the grating is said to be 'blazed') so as to concentrate most of the light (up to about 90%) into one of these spectra.

Diffuse Interstellar Bands

In 1922 Berkeley/Lick Observatory graduate student Mary Lea Heger included two unidentified features in a published list of 'stationary' absorption lines seen in the spectra of distant binary stars. Spectral lines due to stars in a binary system shift back and forth in wavelength owing to the Doppler effect, while the mystery lines did not. Astronomers soon realized that 'stationary' lines are formed in interstellar space and thus do not share the motion of the stars in an orbiting system — but the two features found by Heger remained unidentified. More than a decade later Paul Merrill, who followed Heger as a graduate student at Berkeley/Lick, investigated the unknown features and found about 10 more. Merrill dubbed them diffuse interstellar bands (DIBs) owing to their great widths (as compared with interstellar spectral lines due to atoms and ions).

Now, 80 years after Heger's first notice of the DIBs, more than 200 of the features have been found (see figure 1) — and not even one has been identified. The behavior of the DIBs is consistent with an interstellar origin, in that they grow in strength with distance and total gas abundance, but their wavelengths and widths do not match the spectral features of any known atom, ion or molecule.

Historical developments

Almost immediately following Merrill's initial work on the DIBs in the mid-1930s, several prominent astronomers suggested that molecules in space might be responsible, as this was about the same time when the first simple (two-atom) interstellar molecules were discovered. However, the unknown bands were very broad, not consisting of separate, sharp lines as would be expected from small molecules. A more difficult challenge for the molecular hypothesis was that the density of gas in interstellar space is very low, seemingly too low to allow the formation of complex molecules.

Astronomers turned their attention to another hypothesis: that the DIBs are formed by solid particles in space known as interstellar dust grains. Solid particles can absorb at specific wavelengths to create bands similar to the DIBs, if the particles contain impurity atoms or attached atoms or molecules on their surfaces. For about three decades starting in the 1950s the dust grain hypothesis was favored by most researchers, but again no specific substances or particles could be identified with any of the DIBs. Furthermore, careful examination of specific DIBs failed to reveal some of the properties expected of solid-state absorbers, such as bandwidth and profile variations with varying grain size, or polarization within the bands.

Thus the dust hypothesis was already in trouble when, starting in the 1970s, several factors began to point back in the direction of a molecular origin for the DIBs. The first significant development was the discovery of many new and increasingly complex molecules in dark interstellar clouds, where molecules emit at radio wavelengths, releasing energy gained in collisions with each other. It became apparent that molecules can form and survive in interstellar space, at least in the very densest clouds if not in the more diffuse regions where the DIBs arise. Then a series of papers published in the late 1970s showed how molecules, even relatively small ones, could form broad, featureless spectral bands similar to the DIBs. However, the strongest impetus for the molecular hypothesis came in 1984 with the discovery that large organic molecules are abundant in space, even in diffuse regions. In that year the French scientists Jean Puget and Alain Léger showed that certain interstellar features seen at infrared wavelengths can be attributed to large hydrocarbon molecules, specifically a class known as polycyclic aromatic hydrocarbons (PAHs). Almost immediately several astronomers suggested that PAHs, or more likely their ions (having lost one electron), could produce the DIBs. This hypothesis remains viable, as do other classes of molecules such as carbon chains, which are abundant in dense clouds.

Since the mid-1980s progress has been rapid, for at least two reasons: (1) the availability of very accurate astronomical measurements of the DIBs, taking advantage of new technology in telescopes and light-detecting

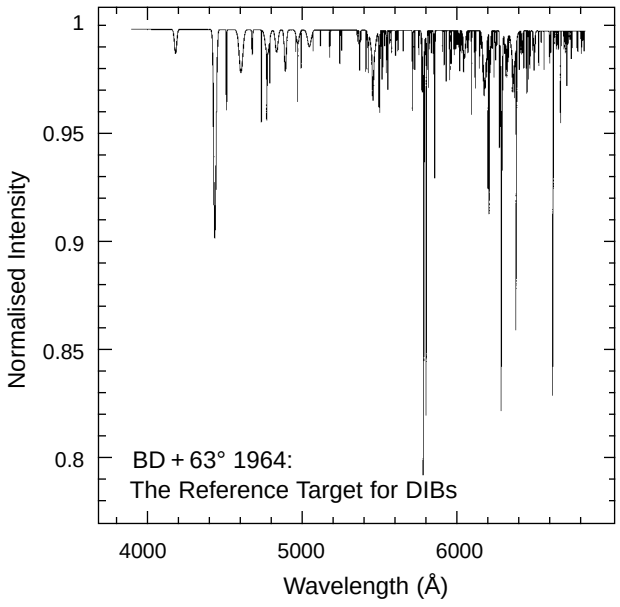

Figure 1. The diffuse interstellar bands in the spectrum of a distant star. All of the dips in the graph shown here are DIBs in the spectrum of the star BD + 63 1964. The particles that create these spectral bands have not been identified, but are thought to be complex organic molecules in interstellar space (O'Tuairisg *et al* (2000), *A&A Suppl.* **142**, 225–238).

devices such as charge-coupled devices; (2) the involvement in DIB research of scientists, such as chemists, from fields other than astronomy.

Properties of the DIBs

Today more than 200 DIBs have been found, and additional weak ones appear almost every time a new level of sensitivity is reached in the observations. All of the DIBs correlate roughly with interstellar parameters such as total gas column density or the extinction of starlight due to interstellar dust — but none correlates perfectly with these quantities or with each other. Subgroups of DIBs have been found to correlate internally better than the bands as a whole, leading to the identification of 'families' that may have a common origin. In any event it has become clear that multiple carriers must be involved, given the sometimes widely disparate behavior of different DIBs.

In general the DIBs are strongest in diffuse interstellar regions rather than the dark, dense clouds where radio-emitting molecules are observed. In fact the DIBs become weaker with increasing cloud density, suggesting that they may be formed by ionized species that become neutral and alter their spectra in denser environments.

The widths of the DIBs range from less than 0.1 nm to nearly 3 nm. Most lie between roughly 400 and 800 nm, with a greater concentration of features toward the longer wavelengths. Features appear in the near-infrared portion of the spectrum as well, although observations there become difficult owing to atmospheric interference. It is not known whether DIBs occur in the ultraviolet because of observational constraints making their detection difficult.

The wavelengths and profiles of the DIBs are, within observational limits, constant. Minor profile variations may be seen from one line of sight to another, but these are usually attributable to Doppler shifts in separate interstellar clouds that contribute to the absorption. A few of the narrower DIBs display substructure in their profiles which is usually interpreted as due to rotational–vibrational spectra of molecules, although other interpretations have been proposed, such as isotopic shifts. The broadest DIBs, which tend to lie toward shorter wavelengths than most of the narrow ones, appear to lack any detectable fine structure. The widths and profiles of these bands have been attributed to natural broadening (damping) in molecules with very short-lived upper states.

In a very few cases some of the DIBs have been seen in emission rather than absorption. The best-known region where such emission has been observed is a carbon-rich reflection nebula called the Red Rectangle. In this nebula wavelength shifts in the DIB emission bands vary with distance from the exciting star in a manner that appears consistent with variations in rotational excitation of molecules.

An order-of-magnitude estimate of the quantities of molecules needed to produce all the observed DIBs places constraints on the elements that may be responsible. Only universally common species such as hydrogen, carbon, nitrogen, oxygen and a few others are viable; other elements are too rare. Thus hydrocarbons or carbon chains, as well as other types of organic molecules, satisfy the abundance constraint and are therefore plausible on these grounds as well as the spectroscopic properties mentioned above.

Current Status and Future Prospects

Ultimately the goal is to create and measure, in the laboratory, the particles that produce the DIBs. Only when species are found whose spectra precisely match the observed interstellar bands (while not predicting features that should be seen in space but are not) will we be able to claim identification. Achieving this goal is a daunting task, given the enormous variety of viable species, each with its own unique spectrum, and given also the practical difficulties involved with laboratory studies of large molecules, especially molecular ions which are favored by many researchers as the most probable candidates for the DIB carriers.

Despite the obstacles, several research groups around the world are pursuing the DIBs, in the laboratory and at the telescope. There have already been some near-misses, i.e. species displaying enough of the required properties to raise hopes, but so far all have fallen by the wayside. However, given the unprecedented current level of interest and intensity of effort in attacking the problem, there is reason for optimism that at least some of the DIBs may be identified soon. When that happens, astronomers will have a new tool for probing the physics and chemistry of interstellar space, probably gaining as well new information on the abundances and types of organic species that were present in space long before life formed on Earth.

Digges, Leonard (*c* 1520–*c* 1559) and Digges, Thomas (1545/6–95)

Both were English astronomers, opticians and military engineers. Thomas was born in Wotton, Kent, England, and incorporated his father's work on optics and ballistics into his own publications. He was tutored by JOHN DEE. In 1573 Thomas Digges published *Alae seu Scalae Mathematicae*, a work on the position of the supernova of 1572, showing it had no parallax, i.e. was at a great distance, beyond the Moon, thus showing that changes took place in the stellar sphere. The observations demonstrate that Digges was the best observer of his time. Digges went on to translate COPERNICUS' works and added his own ideas of an infinite universe with the stars at varying distances in space to his *Perfit Description of the Caelestial Orbes* in 1576.

Dione

A mid-sized icy satellite of Saturn, discovered by Giovanni Cassini in 1684. Its diameter is 1120 km, and it orbits at a distance of 377 000 km. Its density of 1490 kg m^{-3}, the highest of Saturn's mid-sized satellites, indicates a composition of rock and ice. There are two basic terrain types on Dione: cratered terrain and cratered plains; the cratering on the plains indicates that the resurfacing process that created them took place long ago. The largest crater is the 231 km diameter Amata. The plains are crossed by troughs and fissures, the longest being the 394 km Palatine Chasma, which is up to 8 km wide. There are also features that look like the Moon's sinuous rilles (which are known to be collapsed lava tubes), and strange wispy patterns on the surface. A small satellite, Helene, is co-orbital with Dione.

Direct Motion

Angular motion in the prevailing direction, also known as *prograde motion* (as opposed to retrograde motion, in the opposite sense). Motion of a body in the solar system, either axial rotation or orbital revolution, is direct if it is in the same direction as that of the Sun's rotation: counter-clockwise as viewed from the Sun's north pole. The majority of solar system objects show direct motion, which is a relic of the motion of the rotating disk of material from which the Sun and the planets formed. Bodies in direct orbits have orbital inclinations of less than 90°; bodies with direct rotation have axial inclinations of less than 90°. All the major planets, most planetary satellites, all but a handful of asteroids and the majority of comets have direct orbits. Of the major planets, Mercury, Earth, Mars, Jupiter, Saturn and Neptune rotate in the direct sense. Most satellites rotate directly; rotations for asteroids and comets are known only in a small number of cases. The term is also used for the regular movement of solar system bodies from west to east on the celestial sphere.

Compare: retrograde motion.

Disconnection Event

A discontinuity in the gas tail of a comet in which the tail appears to break off from the coma, and a new tail begins to grow. A disconnection event occurs when the comet crosses a sector boundary. Entrained within the solar wind is a magnetic field. As the Sun rotates, the field lines are wound into a spiral pattern. The magnetic field has regions of north and south polarity, and the sector boundary is the two-dimensional surface that separates these regions. It too is wound into a spiral, so a comet can undergo several disconnection events in a single apparition if it makes several crosses of sector boundary lines. For example, Halley's Comet underwent 19 disconnection events at its return in 1986.

Disk Galaxies

Stellar disks are the main structural features of disk galaxies, which we divide into the spiral, S0, and irregular morphological classes. The disks are highly flattened, with approximate circular symmetry. In spiral and irregular galaxies, the disk contains gas as well as stars, and fine structure is common, including the spiral arms which define that class. Our nearest disk galaxy is our own MILKY WAY, a spiral galaxy; the Sun lies in the plane of the disk, about 8 kpc from its center.

The stars and gas of a galaxy disk follow near-circular orbits around the center, in the plane of the disk. The disk does not rotate rigidly like a turntable, but differentially: stars in the outer regions take longer to complete an orbit than those close to the center. The orbital motion of the stars and gas supports the disk against collapse under gravity. Organized rotation dominates all other motions; random velocities account for very little of the kinetic energy, so that disks are dynamically 'cold', or at least 'cool'. In the Milky Way, disk stars near the Sun move at about 200 km s^{-1}, taking about 250 Myr to complete an orbit, but their random motions are typically only 30 km s^{-1}. Because the disks are cool, they tend to be unstable to forming internal substructures such as bars and spiral arms.

Giant disk galaxies, with luminosities more than about $610^9 L_{\dot{o}}$ (our Milky Way is roughly three times brighter), are composite systems. The round inner bulge is much denser than the disk, and 'hotter'; the stars have large random motions. Within the bulge is a yet denser star cluster, the galactic nucleus; some nuclei contain massive black holes at their centers. Giant galaxies follow a morphological sequence, named for its originator, Edwin Hubble; see GALAXIES: CLASSIFICATION. The S0 galaxies have large central bulges or spheroids, and a smooth stellar disk; spiral arms, gas and star formation are normally absent. Along the sequence from Sa through Sb to Sc, the central bulge becomes smaller, while the prominence of the spiral arms increases, along with the fraction of gas and newly formed stars.

Dwarf galaxies are smaller, less luminous, and less massive than the giants. They are also more diffuse, with reduced densities of stars and gas, and they lack the dense round central bulges. At the boundary between dwarfs and giants are the Sd galaxies, with very thin stellar disks, and only rudimentary spiral structure. The trend towards less organized optical structure continues through the Sm Magellanic irregular class to the dwarf irregulars (dIrr), which are the least massive and least luminous, with blue luminosities below $10^8\ L_{\dot{o}}$. All of these classes of dwarf disk galaxies are rich in gas, and have relatively large contributions from young stars.

Structures of galaxy disks

Stellar disks

The Milky Way is the only galaxy where the three-dimensional structure is well known; elsewhere, we see only two-dimensional projections of the galaxies. By observing many galaxies, randomly distributed over all possible viewing angles, we deduce the average three-dimensional structures of the various classes. In disk galaxies that we view nearly face-on, perpendicular to the plane containing the disk, the projected brightness of starlight declines smoothly with radius. At a given wavelength λ, the run of intensity $I_\lambda(r)$ with radius r from the disk center, is roughly exponential: $I_\lambda(r) \approx I(0)\, e^{-r/h_r}$. The *radial scale length* h_r is the e-folding length for the starlight integrated vertically through the disk. In most spiral galaxies, h_r is 1–5 kpc; dwarfs can have h_r<1 kpc while in some peculiar giant galaxies h_r>10 kpc.

In most disk galaxies, near the center where $r<h_r$, the luminosity rises above the inward extrapolation of the exponential law describing the main disk. We can define the disk central brightness $I_\lambda(0)$ by extending the disk model to $r=0$; the total luminosity of the disk is simply $L_\lambda = 2\pi h_r^2 I_\lambda(0)$. Measured values of the central disk brightness are commonly around $I_\lambda^*(0) \approx 150\ L_{\dot{o}}\ pc^{-2}$ in blue light; this is the *Freeman peak*. It is now recognized that the Freeman value reflects an approximate upper bound to disk surface brightness. While few galaxy disks have brighter centers, disks exist with lower surface brightness, ranging down to a few percent of the Freeman luminosity density. These are the *low-surface-brightness* galaxies. One caution: although it is usual to extrapolate the exponential law in this way, it is not clear if the stellar disks really extend into the central galaxy.

We see our own galaxy, the Milky Way, as a luminous path across the sky on a dark night; the Sun is near the mid-plane of our disk, so we observe the stellar disk in projection from within. The disks of other galaxies also appear as narrow bands of light when we see them edge-on. If an edge-on disk contains only stars, with no interstellar matter to block light, we can use brightness maps to derive the distribution of stellar density 'above' the mid-plane in the z-direction.

Stellar disks have complicated vertical structures. In our own Milky Way, the youngest stars are concentrated near the disk mid-plane, with exponential *scale heights* h_z<0.1–0.2 kpc (see GALACTIC THIN DISC). Older stars form a 'thick disk' (see GALACTIC THICK DISC) with a scale height $h_z \approx 1$ kpc. The vertical scale height of each component of a stellar disk depends on its velocity dispersion perpendicular to the disk; higher speeds yield thicker disks, since the stars can travel further from the midplane. Young stars are born from clouds of gas that are dynamically 'cold'; they have little vertical kinetic energy, and are confined close to the mid-plane. As they orbit, stars feel the gravitational forces from large lumps of gas and

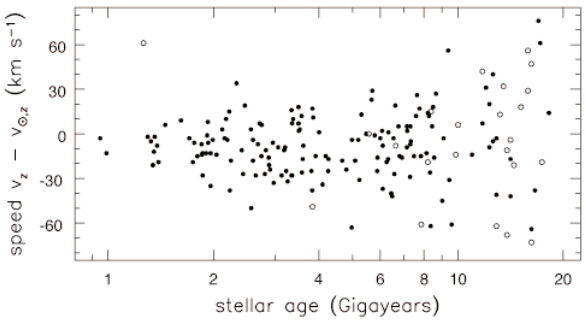

Figure 1. For nearby main-sequence F stars, velocity v_z–$v_{z'\odot}$ perpendicular to the Galactic plane, measured relative to the Sun. Open circles show stars with less than 1/4 of the Sun's iron abundance. Older stars tend to be metal-poor and faster-moving. Data from Edvardsson *et al* 1993 *Astron. Astrophys.* **275** 101.

stars that are present in the spiral arms. The repeated tugs 'heat' them, increasing their random motions both vertically and in the plane of the disk: see figure 1.

In external galaxies, the vertical light distributions is often nearly exponential at large z, but flattens near the mid-plane. The average vertical scale heights derived from fits to the luminosity profiles of giant disks are smaller than the radial scale lengths, typically by factors of ≈5–10. Some 'superthin' Sd galaxies have even larger ratios, while irregular galaxies are typically fluffy: see figure 2. When we observe a galaxy disk edge-on, there is the additional complication that we integrate the light over a range of radii. The projected light distribution along the mid-plane $z = 0$ is not proportional to the surface brightness $I_\lambda(r)$ that we would measure if the galaxy was seen face-on. For example, the radial brightness profile of an exponential disk that is edge-on will be fit by modified Bessel functions, which have a shallower drop-off with radius than the exponential distribution.

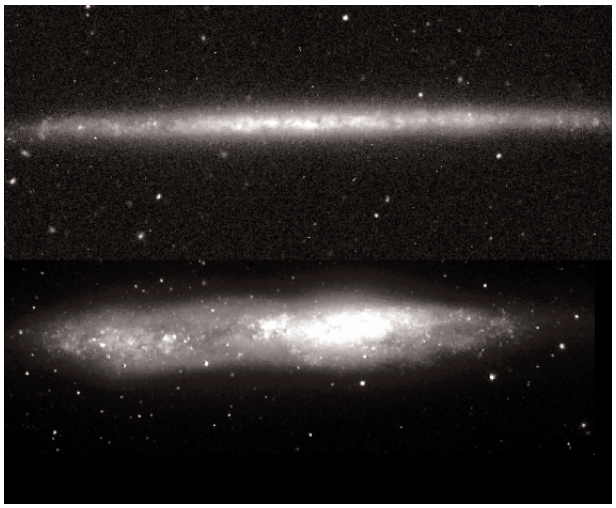

Figure 2. *B*-band images of two very different disk galaxies. Top: 'superthin' Sd UGC 7321, viewed ≲2° from edge-on. This is a small galaxy, with $L_B \approx 10^9\ L_\odot$ (L Matthews, WIYN telescope). Bottom: barred Magellanic or irregular NGC 55, about 10° from edge-on. Its linear size is about half that of UGC 7321, while it is twice as luminous. Note the fluffy disk, and off-center concentration of light (A Ferguson).

Figure 3. *V*-band image of Sa galaxy NGC 4594, the 'Sombrero'. This is a luminous galaxy ($L_V \approx 8$–$10^{10}\ L_\odot$) with a very large bulge, and numerous globular star clusters around it (A Cole, WIYN telescope).

Gas disks

Except in the S0 galaxies, the disk contains gas as well as stars. The interstellar medium of a disk galaxy like the Milky Way is richly varied. It includes phases ranging from molecular cloud complexes with densities of ~10^2 particles cm^{-3}, to diffuse highly ionized gas with densities of ~10^{-2} cm^{-3} and temperatures >10^6 K. The gas is also threaded with energetically significant magnetic fields, and bathed in the cosmic rays trapped by the field. Interstellar matter is perhaps most readily seen as dark clouds or lanes, where dust grains associated with the gas block our view of the stars behind. In the southern and northern Milky Way, dust is apparent as individual dark clouds, such as the 'coal sacks', along the plane of the bright disk. In optical pictures of edge-on disk galaxies such as figure 3, dust in the disk causes the characteristic dark band across the mid-plane. See also INTERSTELLAR MATTER.

Interstellar dust grains (see INTERSTELLAR GRAINS) absorb and scatter starlight at wavelengths from the near infrared to soft x-rays. Interstellar dust grains are small—most have diameters between 0.001 μm and 1 μm—and dust opacity rises rapidly with decreasing wavelength. We get our best views of the distribution of stars in

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

spiral galaxies in the infrared spectral region at λ~2 μm, the longest wavelengths where direct stellar radiation is still important. In the thermal infrared region, at wavelengths 5–300 μm, we see radiation from the dust grains themselves, warmed by the starlight that they have absorbed; most of the power is in the far infrared (FIR), at λ>50 μm. Images of galaxies at FIR wavelengths show emission where there are stellar (or other) heating sources, and the dust absorbs their light efficiently. The most spectacular star-forming disk galaxies, the STARBURST GALAXIES such as M82, contain so much dusty gas that it blocks starlight even at infrared wavelengths. There, the distributions of young stars can only be mapped from the FIR emission, and the radio emission of ionized gas near massive stars, or of the young remnants of supernova explosions.

A typical giant spiral galaxy has about 5–10×10^9 $M_\odot$ of cool interstellar gas. About half of this is clumped into dense regions, close to the midplane of the disk, where hydrogen is in molecular form (H_2). Young stars are born in these cool molecular clouds. Since H_2 is a symmetric molecule, it produces no strong emission, and its ultraviolet absorption bands become difficult to observe in dense regions of the interstellar medium. The locations and amount of H_2 are usually derived from observations of tracer molecules which do produce radio frequency line emission, such as CO or HCN. Molecular gas is usually concentrated in the inner galaxy, where it forms a very thin disk, with scale height h_z<0.1–0.3 kpc.

The remainder of the interstellar gas is more diffusely distributed; most of it is neutral (H I) or ionized (H II) hydrogen. The spatial distribution of the H I in disk galaxies is the most easily measured, through the hyperfine 21 cm emission line. This component is usually quite thin with vertical scale height h_z<1 kpc, and a radial distribution that extends further from the center than the stellar disk. The outer regions of most galaxy disks appear to consist mainly of H I gas. Warm ionized gas, within 1–2 kpc of the midplane, is traced from the recombination emission lines of hydrogen. The disk is surrounded by a much hotter diffuse halo of gas at 10^5–10^6 K; we detect it in x–ray emission, or by ultraviolet absorption spectroscopy of resonance lines produced by heavier elements within the hot gas.

The first unambiguous evidence for a giant halo of hot gas around a nearby spiral galaxy much like our own Milky Way was found by astronomers using NASA's CHANDRA X-RAY OBSERVATORY. Chandra found a diffuse halo of x–ray gas, radiating at a temperature of almost 3 million degrees, around galaxy NGC 4631, approximately 25 million light years from Earth. The Chandra image reveals a halo of hot gas that extends for approximately 25 000 light years above the disk of the galaxy. One important feature of the x–ray emission from NGC 4631 is that it closely resembles the overall size and shape seen in the radio emission from the galaxy. This indicates that there may be a close connection between the outflows of hot gas, seen in x–rays, and the galaxy's magnetic field, revealed by radio emission. A Hubble image of NGC 4631 shows filamentary, loop–like structures enclosing enhanced x–ray–emitting gas and emanating from regions of recent star formation in the galaxy's disk. Together, these data clearly show that the hot gas is heated by clusters of massive stars and is now expanding into the halo of the galaxy.

The interplay between the gaseous and stellar components of disks is extremely complicated. A gaseous disk experiences dissipation, and can radiate away the energy associated with random motions, so that it tends to collapse in the vertical direction. However, energy and momentum are fed into the interstellar medium, by fast stellar winds, ionizing radiation, and supernova explosions from massive stars. These increase the internal energy of the gas, causing it to expand vertically; in extreme cases it can even escape as a galactic wind. Since stars are made from dense cool gas, star formation can be

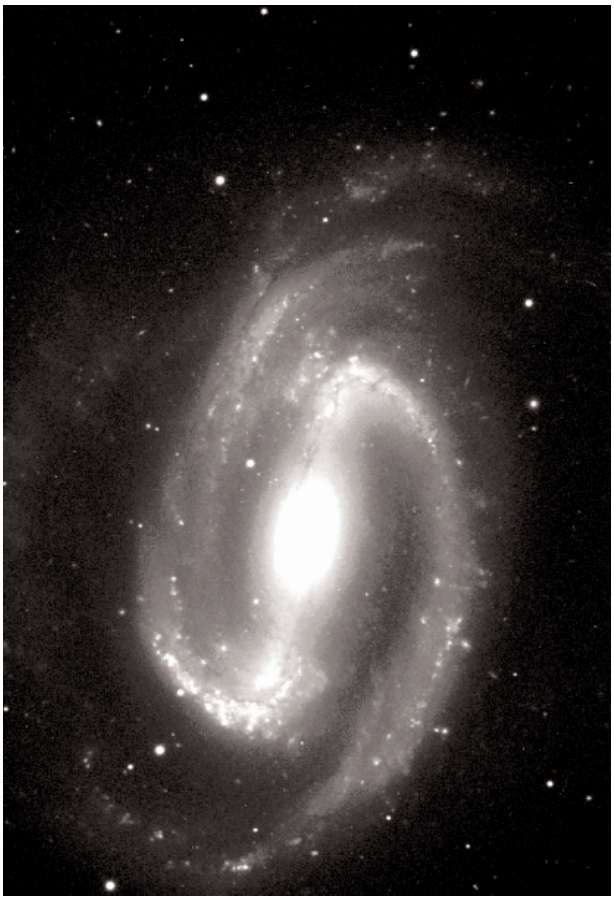

Figure 4. The barred galaxy NGC 1300, classified SBb or SBbc, with 'grand design' spiral arms. The arms trail; their tips point opposite to the galaxy's sense of rotation. Note the dust lanes on the leading edge of the bar, and on the concave sides of the spiral arms (WIYN telescope).

a self-regulating process. If many young stars are made, they can blow the gas away, or heat it so much as to prevent further starbirth. See also GAS IN GALAXIES.

Spiral arms and bars

The photogenic arms of spiral galaxies are the most striking luminous structures in any galaxy atlas. In a minority of giant galaxies, such as M81 or NGC 1300 (see figure 4), we see a 'grand design' spiral: a pair of well-defined arms winds over azimuth angles of more than 90° and extends in radius over much of the optically visible stellar disk. More frequently, the spiral arms are broken up into shorter segments, and more than two arms are present. In 'flocculent' disks, the spiral consists of many small arm fragments; there is no organized spiral structure on large scales. Gas seems to be essential to forming spiral arms; the S0 galaxies lack both gas and spiral pattern. Strong spiral arms form most readily in the rapidly rotating massive disks of luminous galaxies. Lower luminosity (and less massive) galaxies have messy spiral patterns, or none. The Sd systems often have ill-defined arms, while spiral arms are totally absent in the low mass dIrr galaxies. The decline in spiral arm intensity and frequency with decreasing galaxy mass suggests that gravity is important in shaping the spiral structure.

To the surprise of astronomers, the galaxy NGC 4622 appears to be rotating in the opposite direction to what they expected. Astronomers are puzzled by the clockwise rotation because of the direction the outer spiral arms are pointing. Most spiral galaxies have arms of gas and stars that trail behind as they turn. But this galaxy has two leading outer arms that point toward the direction of the galaxy's clockwise rotation. To add to the conundrum, NGC 4622 also has a trailing inner arm that is wrapped around the galaxy in the opposite direction it is rotating. Astronomers suspect that NGC 4622 interacted with another galaxy. Its two outer arms are lopsided, meaning that something disturbed it. The new Hubble image suggests that NGC 4622 consumed a small companion galaxy. The galaxy's core provides new evidence for a merger between NGC 4622 and a smaller galaxy. This information could be the key to understanding the unusual leading arms.

Spiral arms can be characterized by their pitch angle, the angle at which the arm cuts through a circle around the galaxy center. Arms in Sa galaxies are tightly wound, with small pitch angles, while those in later-type spirals are more open, with pitch angles of 10–30°. Spiral arms generally trail, with the tips of the arms pointing opposite to the direction of galactic rotation. In figure 4, we see dark dust lanes on the concave sides of the spiral arms; these show where the disk gas is compressed as it flows into the arms. Thus the spiral stands out when observed in H I, or tracers of molecular gas such as CO emission. The bright young stars which make the spiral arms so prominent have been formed from this compressed gas.

Massive stars have short lives; those hot enough to ionize the gas around them last less than 5 Myr, and lifetimes are generally <30 Myr. This is only about 10–20% of a galactic rotation period. So the hot stars that we see in the grand-design spiral arms must have been born in or near them; if they were made elsewhere in the disk, they would die before they could be concentrated into the spiral arms. A classic problem is whether spiral arms stimulate star formation, or simply act to organize it. In the former case, we would expect star formation to be more vigorous in galaxies with grand-design spiral patterns than in flocculent galaxies. But observational comparisons show no significant difference in the rates; the arms seem to act more as star formation organizers.

The young stars in spiral arms radiate 10–100 times as much power per unit mass as older stellar populations, in which the most massive stars are no longer present. Even small fractions of young stars can have major observable consequences. These effects are most pronounced in blue and ultraviolet light, where these hot stars produce most of their luminosity. Young massive stars also photoionize the gas from which they were born, producing brilliant ionized nebulae, known as H II regions. The H II regions are excellent tracers of spiral structure, since they are easily observed in their bright atomic emission lines, from hydrogen recombination and collisionally excited lines of common elements such as nitrogen, oxygen, and sulfur.

About half of all disk galaxies show a central linear bar, containing up to a third of the total light. The ratio of the long to the short axis of the bar can be as extreme as 1:5, as in figure 4. Gas is not required for a bar: the disks of S0 galaxies are as likely to be barred as are the gas-rich spiral galaxies. In Hubble's classification, 'B' is added to indicate a bar; NGC 1300 is of type SBb. Bars are the offspring of stellar disks; they appear to be vertically thin, like the disk, and not round like the bulge. The main bars of giant galaxies typically extend to radii of a few kiloparsecs.

Bulges and nuclei

In less luminous Sc and Sd galaxies, and some dwarfs, the approximately exponential disk extends to the center of the galaxy; for these pure disks, the central surface brightness is simply $I_\lambda(0)$. Low-luminosity galaxies are often asymmetric, with no well-defined center; e.g. the brightest region may not lie at the kinematic center of the system. The Large Magellanic Cloud is a prime example of an off-center disk galaxy; here, the center of rotation is outside the bright stellar bar. The irregular galaxy NGC 55, in figure 2, also shows an off-center concentration of light.

By contrast, most giant disk galaxies are reasonably symmetric. Extra light is also present in the inner few kiloparsecs, above that expected from the main disk. This is the central *bulge*: a spheroidal stellar system normally consisting of stars with ages ≧3 Gyr (see GALACTIC BULGE). Bulges typically contain little gas, except near their centers. Spheroidal bulges are rotating, but the large random stellar motions allow them to be thicker in the *z*-direction, perpendicular to the disk midplane, than the surrounding stellar disk. The 'Sombrero', shown in figure 3, is an outstanding example of a disk embedded in an unusually large oblate stellar bulge. Smaller bulges, like those of the Milky Way or our neighbor Sb galaxy M31, are much more common. By contrast, some spirals have inner disks. Like bulges, these small disks have much higher surface brightness than the main stellar disk; but they are relatively flat, roughly axisymmetric, and dynamically 'cooler' than spheroidal bulges. Inner disks often support star formation and have their own spiral structure.

Images of the centers of disk galaxies taken at high angular resolution reveal a variety of structures. In some galaxies, small nuclear bars are present, often nested within a larger main bar; these have sizes of <1 kpc. The available evidence suggests the nuclear bars are independent entities, that do not rotate at the same rate as their main bars. At or near the very center is the *nucleus*, a tiny (r<10 pc) object containing the highest density of stars in the galaxy, up to $10^6\ L_{\odot}\ \mathrm{pc}^{-3}$ (see GALACTIC NUCLEUS). Sometimes a massive black hole, with M_{BH}>$10^6\ M_{\odot}$, is also present as well. When gas or stars are swallowed by the black hole, huge amounts of gravitational energy can be released, producing a luminous active galactic nucleus (AGN) that can compete with the power output of all of the stars in the galaxy. However, most nuclei are not AGNs, and derive much of their luminosities from the stars they contain. As a result they are relatively faint, with optical luminosities of 10^6–$10^8\ L_{\odot}$.

Dynamics

The stars of a galaxy move under gravity; other forces are rarely important. In the disk, stars are widely separated in space, so we have the additional simplification that close collisions between them are rare, and can be safely ignored. Thus their motions can be studied as a response to the galaxy's mean gravitational field, which must be computed self-consistently from the mass distribution; this is a challenge, since the system has ~10^{11} particles (see also STELLAR DYNAMICS). By contrast, gas responds both to gravity and to hydromagnetic forces. Since dense gas clouds do collide, they can dissipate the energy of random motions. Because of this, cool disk gas rapidly settles onto closed periodic orbits about the galaxy center; in an axisymmetric disk, these are the circular orbits.

Rotation and mass distribution

We can use Doppler-shifted emission lines from the gas to find the mass of a disk galaxy. If we measure the speed $V(r)$ of gas in a circular orbit at radius r, we can use the radial-force equation $V^2(r)/r = GM(<r)/r^2$ (which is exact in a spherical system) to make a rough estimate of the mass $M(<r)$ within that radius. In giant disk galaxies, $V(r)$ climbs steeply over the inner kiloparsec or so, to a maximum that is typically at V_{max}~150–300 km s^{-1}, and then stays roughly constant. In dwarfs, the rise is more gradual and peak speeds are lower.

We can compare the observed rotation curves of disk galaxies with what we would expect if their mass had been concentrated entirely in the stars and gas. Even when the assumed ratio of mass to light in the disk is adjusted so that gas and luminous stars account for as much of the galaxy's rotation as possible, we would expect the rotation speed to fall beyond 2–3 times the scale length hr of the exponential stellar disk. Instead, we usually see that $V(r)$ remains approximately constant to the edge of the gas disk, implying that $M(<r)$ continues to rise; the outer parts of the galaxy contain much mass but emit little light. A spherical halo of *dark matter* is generally invoked to provide the required extra mass. Dark matter usually accounts for between 50% and 90% of a disk galaxy's total measured mass, with dwarf galaxies generally having a higher proportion than giants. See also DARK MATTER IN GALAXIES.

More luminous galaxies rotate faster on average, which tells us that they are more massive. The peak rotation speed V_{max} increases with the galaxy's luminosity L, roughly as $L : V_{\mathrm{max}}{}^{\alpha}$, with α~4: this is the *Tully–Fisher relation*. If galaxies contained no dark matter, we might be able to understand the TULLY–FISHER RELATION. But since the speed V_{max} is set largely by the unseen material, while the luminosity comes mainly from the stellar disk, the link between them is puzzling. Nevertheless, the Tully–Fisher relation is very useful in finding distances to galaxies and galaxy groups, since we can estimate the true luminosity of a galaxy from its measured rotation speed.

Disk stability

Galaxy disks live on the edge of gravitational instability; galactic bars, and the spiral arms, are the consequences. The mutual gravitational attraction of disk stars and gas clouds tends to pull them together. On the other hand, since the period of an orbit around the galaxy center increases with radius, the disk's rotation tries to shear any feature into a trailing spiral arm segment. In a 'cool' disk, where the random motion of the stars is small enough that it does not take them outside the spiral arms, their gravity can reinforce a spiral pattern by attracting other stars into it, and so help the spiral to grow. But if the disk contains little mass, or its stars have large random motions, then gravity will be

insufficient to amplify a spiral, and no strong arms will develop.

Locally, an axisymmetric disk is unstable, and a spiral will grow, if the Toomre 'Q' parameter $Q = \kappa\sigma_R/3.36G\Sigma \lesssim 1$. This criterion specifies that the dispersion σ_R of stellar velocities in the radial direction must be small enough by comparison with the surface density Σ of mass in the disk; κ is the epicyclic frequency with which a star oscillates radially about the nearest circular orbit, and G is the gravitational constant. Computer simulations of a 'cool' axisymmetric disk of 'stars' attracting each other by gravity, and initially following nearly circular orbits, show that a spiral pattern generally grows if $Q \lesssim 1$. As it does so, the stars develop larger random motions, and Q rises; so we never expect to see a stellar disk with $Q<1$. Near the Sun, the density in the disk $\Sigma \sim 50$ $M_\odot$ pc^{-2}, and $\kappa \approx 35$ km s^{-1} kpc^{-1}, while for stars about as old as the Sun, the velocity dispersion $\sigma_R \approx 30$ km s^{-1}. Hence $Q \sim 1.4$, which is safely greater than unity.

The simulated disks generally grow a two-armed spiral, and often a straight central bar in addition. The 'stars' stream through the spiral, slowing down and lingering in its gravitational potential well, and then pass on through it; the spiral is a *density wave*, a stellar traffic jam. We believe that the same is true in real galaxies. The pattern of the arms turns in the same sense as the disk's rotation, at some angular rate Ω_p, which is set by the angular frequency of rotation $\Omega(r)$ and the epicyclic frequency $\kappa(r)$ in the region where the spiral is strong.

Why do the arms of a spiral galaxy trail, pointing against the direction of galactic rotation? When a trailing spiral is present, gravitational forces cause the inner parts of the disk to exert a torque on the outer disk, which transfers angular momentum outward and allows material at small radii to move inward. The spiral torques decrease the energy of the disk's rotational motion, transferring it to increase the random speeds of the stars. As the disk 'heats up', the spiral eventually disappears. The disk of an S0 galaxy, where no gas is present, would probably behave in the same way: any spiral pattern would be short lived. But in a gas-rich disk, stars freshly born from the cool gas have very small random speeds. Continued addition of these new stars is probably important in prolonging the life of a spiral pattern, or in re-creating it periodically.

The gravitational pull of the spiral arms affects gas even more strongly than the stellar disk, because the random speeds of gas clouds are only 5–10 km s^{-1}, much lower than for the stars. Except immediately around the corotation radius, where the angular speed $\Omega(r)$ of a circular orbit is close to Ω_p, the linear speed $r[\Omega(r)-\Omega_p]$ with which gas moves into the spiral arm is supersonic. Shocks develop, compressing the gas enormously as it flows into the arm; we see dark dust lanes there. After about 10 Myr, young stars are born in the compressed gas and begin to shine; the Hα emission from gas ionized by these stars is not concentrated on top of the dust lane, but 'downstream' of it. Radiation from the hottest of these stars also splits some of the H_2 molecules apart into atomic hydrogen, H I.

Like spirals, the figure of a galactic bar is not static, but rotates with some pattern speed Ω_p. Unlike spiral arms, a bar truly captures its stars. Within the bar, stars and gas no longer follow near-circular paths, but are trapped near elongated orbits that close on themselves as seen by an observer moving with the bar's rotation. Disk gas cannot flow in toward the galaxy center unless it can get rid of its angular momentum; the strongly asymmetric gravitational forces of a bar help it to do just that. The closed oval orbits converge on each other near the ends of the bar. As gas on the orbits approaches those regions, shocks form. The gas is compressed, and we see dark dust lanes, like those along the leading edge of the bar in figure 4. In the shock, the gas loses part of its energy of forward motion as heat, so it drops down onto more tightly bound orbits closer to the center of the galaxy. Bars may be important in feeding gas in towards the central galaxy.

History

Near the Sun, the oldest disk stars are about 10 Gyr old. By examining the number of stars of each mass that are present today, we can deduce that the Milky Way's disk has been making new stars at a roughly constant rate over the last few gigayears. We live in an Sc (or Sbc) spiral galaxy; the disks of Sd galaxies, and the irregulars, are bluer than ours, implying a larger proportion of newly formed stars. Either their rates of star formation have increased recently, or they simply began their star-forming histories later. The redder colors of Sa and S0 galaxies tell us that star formation in their disks is decreasing; by now, most or all of their gas supply is used up.

Near the Sun, figure 1 shows that younger stars contain a larger proportion of elements heavier than helium. The disk has formed successive generations of stars, each producing metals to contribute to the already enriched interstellar gas. In all but the lowest-luminosity disk galaxies, we see a color gradient; the centers are redder than the outer parts. This is because the inner parts contain both a larger proportion of old stars, and stars that are richer in heavy elements. The bulges and inner disks have already made many generations of stars, while the outer disks have lagged behind, producing their stars more slowly, and remaining gas-rich to the present day. See also GALAXY EVOLUTION.

Galaxy formation: inside-out or outside-in?

How might a galaxy like our own Milky Way come into being, out of the hydrogen and helium gas resulting from the Big Bang? Some would argue that giant disk galaxies

Dirac House, Temple Back, Bristol, BS21 6BE, UK

have grown outward from their central parts (see GALAXY FORMATION). The dense inner bulge, with its low specific angular momentum, formed early on, from a denser-than-average lump of gas that collapsed under its own gravity; it rapidly used up all its gas in forming stars. The disk material, which has more angular momentum per unit mass, would have fallen in later, from greater distances. It must have remained gaseous until almost all its random motion had been dissipated, allowing the material to move inwards and settle onto circular orbits in a thin disk. Only then could the oldest disk stars have been born. Perhaps the disks are still being assembled today, as clouds of cool gas fall in, renewing the supply of raw material to make new stars. The dark matter, unable to dissipate energy, could not fall inwards; hence the dark halo is less concentrated to the galaxy center than are the luminous stars and gas.

Other astronomers point out that the stars of the bulge do not seem to predate the oldest disk stars near the Sun. They offer an alternative idea: the disk formed first, and the bulge grew within it. The disk gas would have flowed slowly inwards, perhaps coaxed towards the center by spiral arms or a galactic bar. When the inner part of the disk had reached a sufficient density, it would have become unstable and formed a bar, which then puffed up vertically into a bulge. This model has received some support from computer simulations. Also, in some bulges the gas is seen to follow oval orbits similar to those in galactic bars, as expected if these bulges are in fact thickened bars. The 'inside-out' enthusiasts retort that the bulge of a galaxy like the Sombrero (figure 3) is much more luminous than the disk, and so is unlikely to be an outgrowth from it. There may be no single route to making a disk galaxy.

Dispersion

In optics, the spreading of a mixture of wavelengths of light (colors) into its consituent wavelengths. The refractive index of a medium (e.g. glass), which determines the extent to which a ray of light is deflected when it enters that medium at any angle other than perpendicular to its surface, is the ratio of the speed of light in a vacuum to the speed of light in a medium. Because different wavelengths of light travel at different speeds in a medium (they all travel at the same speed in a vacuum), the refractive index of a medium is wavelength dependent. Dispersion is a measure of the extent to which refractive index varies with wavelength.

When white light (a mixture of wavelengths) passes through a glass prism, the different wavelengths are refracted by differing amounts and are spread out into a band of wavelengths (a 'rainbow' band of colors), which is called a spectrum. The dispersion of a spectrograph (a device for producing a spectrum) is a measure of the extent to which the various wavelengths are spread out at the focal plane of the instrument. For a particular operating wavelength, λ, dispersion $= \delta\lambda/\delta x$, where $\delta\lambda$ is the change in wavelength over a distance δx along the length of the spectrum. It is usually expressed in nanometers (nm) of wavelength per millimeter (mm) of length (i.e. nm mm^{-1}). The dispersions of astronomical spectrographs usually lie in the range from about 200 nm mm^{-1} to about 0.01 nm mm^{-1}, the lower dispersions (more than a few tens of nanometers per millimeter) generally being useful only for survey work.

The wavelength dependence of refractive index (i.e. dispersion) is also responsible for preventing a simple lens from focusing all wavelengths of light at the same point, the spread of focal points for different wavelengths being called chromatic aberration. Dispersion also arises in the phenomenon of diffraction (different wavelengths are diffracted by different amounts) and when light of different wavelengths is scattered from small particles (the shorter the wavelength, the greater the degree of scattering).

Distances (from Antiquity to 1900)

Ancient views on the scale of the planetary system

Before the dissemination of Greek culture in the 'Hellenistic' period that followed the conquests of Alexander the Great in the late 4th century BC, notions of astronomical distances were purely speculative. Although ancient cultures developed accurate surveying methods, the mathematical techniques required for astronomical distance measurement came only with formal Euclidian geometry.

For the Greeks, who believed the Earth to be spherical and at rest at the center of the cosmos, the baseline for distances within the planetary system was the Earth's radius. ERATOSTHENES OF CYRENE (*ca* 276–195 BC) devised a method and made the first measurement of the Earth's dimensions (see figure 1). He knew that at the summer solstice the Sun cast its rays directly down a well in the Egyptian town of Syene, while at Alexandria, further north and on roughly the same meridian, the sunlight falling on a gnomon cast a shadow of 1/50 of a circle. Assuming that Syene was 5000 stades south of Alexandria, and knowing that distance to be 1/50 of the Earth's circumference, Eratosthenes calculated the circumference to be 250 000 stades. Depending on the length of a stade—there is uncertainty about which value he employed—he may have been within 8% or even better of the modern value.

ARISTARCHUS OF SAMOS (*ca* 310–230 BC) provided two elegant geometric demonstrations concerning the scale of the cosmos; both would remain central to astronomical thought until the 17th century. First, Aristarchus recognized that the relationship between the Sun's and Moon's positions at quadrature provides a means to calculate their relative distances from Earth (see figure 2). For then the angle Sun–Moon–Earth is 90°, and so if the observer measures the angle Moon–Earth–Sun, then the shape of the triangle will be known, and this will give the ratio of the lengths of the Earth–Moon and Earth–Sun distances.

Aristarchus adopted 87° for the second angle and concluded that the Sun was some 19 times more distant than the Moon. There are two practical problems with this method: it is extremely difficult to know the moment of quadrature by observing when the terminator is precisely at the half-way point on the Moon's face and it is no easy task to observe the Moon–Earth–Sun angle at that time. In fact, Aristarchus's value of 87° may have been to illustrate his method rather than the result of actual measurement.

Aristarchus's second demonstration used eclipse geometry to determine the absolute sizes of the Moon and Sun. During a total solar ECLIPSE, Sun and Moon subtend the same angle, so the ratio of their apparent diameters is the same as the ratio of their distances, which he believed to be 19:1. To obtain absolute distances, he analyzed the situation during a total lunar eclipse, assuming the width of the shadow cone at the Moon's distance to be twice the lunar diameter. From his analysis, he concluded,

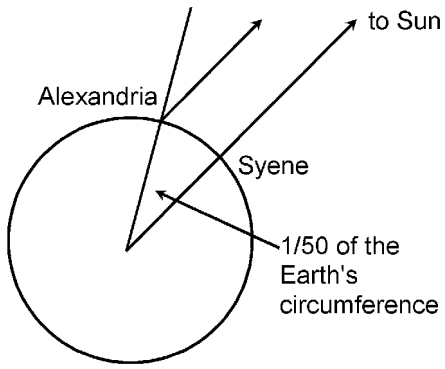

Figure 1.

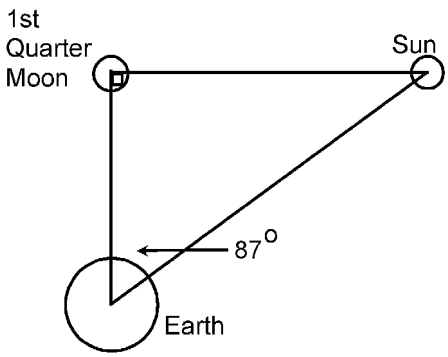

Figure 2.

in mean terms, the Moon's diameter to be about one-third that of the Earth, and the Sun's some $6\frac{3}{4}$ times the Earth's. Curiously, Aristarchus does not calculate the absolute distances in his treatise, but, given a lunar apparent diameter of $\frac{1}{2}^\circ$, and since this was two-thirds the radius of the Earth, its distance was some 80 Earth radii; the Sun's distance (19 times greater than the Moon's) was therefore about 1520 Earth radii.

Hellenistic astronomers recognized the importance of the Sun's PARALLAX, the angle subtended by the Earth's radius as seen from the center of the Sun. Ideally, one could determine this by viewing the Sun from two distant locations at the same time, or by observing from the same location several hours apart. Since the Earth's radius was known, the absolute distance to the Sun could be calculated if this angle were determined. However, measuring parallax by direct observation of the Sun is impossible, as the Sun's atmosphere does not provide a distinct 'edge', and the angle is so small that naked-eye instruments would be useless. HIPPARCHUS of Rhodes (*fl* 141–127 BC), the greatest influence on Ptolemy, developed alternative methods. Using solar eclipse observations taken from two locations, he calculated the lunar parallax, giving him minimum and maximum distances to the Moon in Earth radii. By a somewhat different employment of Aristarchus's eclipse diagram, and *assuming* a solar

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

parallax of 7 arcmin as the smallest parallactic angle that might be visible, he found a slightly smaller absolute lunar mean distance, just over 67 Earth radii.

PTOLEMY (*fl* AD 127–141) knew of Hipparchus's methods, but attacked the problem in a different way. Studying lunar eclipse data, he was able to obtain the lunar parallax and a (maximum) distance of a little more than 64 Earth radii. By using the eclipse diagram, the solar parallax could then be calculated, which allowed the Sun's absolute distance to be determined. This came to 1210 Earth radii (giving a parallax of nearly 3 arcmin), very close to the 19 times the lunar distance that Aristarchus had calculated. This has suggested to some modern historians that Ptolemy chose his values carefully to obtain the required result. In any event, he could not have observed solar parallax directly, so while his lunar distance is reasonable, his solar distance is an order of magnitude too small.

The order and sizes of the planets

Greek astronomers were largely agreed on the order in which the planets lay in their heights above the Earth. The Moon, being so large and having the shortest SIDEREAL PERIOD, was the closest object. The Sun, although it subtended approximately the same visual angle, took a year to complete its circuit of the sky, so was further away. Mars, Jupiter and Saturn had increasingly longer sidereal periods, so it seemed reasonable to locate them beyond the Sun and in that order, while the stars lay on the outermost sphere. However, since Mercury, Venus and the Sun all have a sidereal period of 1 yr, there was no compelling reason to order them in any particular way. In Ptolemy's *Almagest* the motion of each planet was represented by its own geometrical model, and so in this work Ptolemy did not need to commit himself to any particular order, but, in his later *Hypotheses of the Planets*, he argued for the order Moon–Mercury–Venus–Sun. He also provided a physical picture of the universe similar to the concentric material spheres of Aristotle. Believing the cosmos to be a plenum (a space filled with matter as opposed to a void), he held that the outer surface of one planetary sphere coincided with the inner surface of the next sphere, so that the cosmos was a nesting set of such spheres. Thus he took the lunar apogee to be equal to the perigee of Mercury, and this distance was the radius of both the outer boundary of the lunar sphere and the inner boundary of the sphere of Mercury. Mercury's apogee, similarly, was equal to the perigee of Venus, and so on.

The ratio of the perigee to the apogee of any particular planet could be calculated from its geometrical model. Ptolemy's nesting spheres therefore allowed him to derive absolute distances for every planet if he could calibrate his scheme by knowing the actual value of any one of the parameters. As he had already calculated that the Moon's apogee distance was just over 64 Earth radii, the remaining distances followed. The Sun's mean distance was 1210 Earth radii, or a little less than 8 million kilometers using the modern value for the Earth's radius. The outer boundary of Saturn's sphere was 19 865 radii.

Ptolemy similarly provided the angular and actual diameters of the Sun, Moon and planets, although the angular diameters of the planets were in fact subjective and based essentially on their perceived brightnesses. Saturn, for example, was said to have an angular diameter 1/18 that of the Sun when the planet was at its mean distance. As this mean distance was known, it followed that Saturn's actual diameter was about 4.3 times that of the Earth.

Since the 'fixed' stars were immediately beyond the outer boundary of Saturn's sphere, they were some 20 000 Earth radii above the Earth. Ptolemy estimated the apparent diameters of the first-magnitude stars to be 1/20 that of the Sun, and from this he calculated their volumes to be over 94 times that of the Earth.

Islamic astronomers did little more than tinker with these values (see also ISLAMIC ASTRONOMY). Al-Farghani for example in the 9th century estimated the apparent diameters of stars of lesser magnitudes, and concluded that a sixth-magnitude star had a volume 18 times that of the Earth.

Latin translations of Arabic versions of Ptolemy and his Muslim commentators became widely known in western Europe during the 12th and 13th centuries. While few European astronomers of the time could deal with the complexities of the *Almagest*, most educated people were aware of the nesting sphere arrangement and its distance scale.

Distances in the Copernican system

The heliocentric model of the planetary system, published in 1543 by NICOLAUS COPERNICUS (1473–1543) in his *De revolutionibus orbium coelestium*, established by elementary geometry not only a unique ordering of the planets but their (broadly correct) relative distances, in multiples of the Earth–Sun distance, later termed the astronomical unit. In Ptolemaic astronomy, the sphere of the Moon served to calibrate the entire system, but in Copernican astronomy lunar motion was now referred to the Earth, and was no longer part of the planetary order. However, Copernicus was satisfied with the ancient value of the solar parallax, 3 arcmin, and as a result the radius of orbit of the outermost planet, Saturn, was for him little more than half the size it had been for Ptolemy.

There was no observational compulsion to prefer Copernicus over Ptolemy. On the contrary: if Copernicus was correct, then one should be able to detect annual or stellar parallax, the apparent movements of the stars that one would expect to see if they were being observed by astronomers located on an Earth that was moving in annual orbit, and this no one succeeded in doing. There were two possible inferences: either Copernicus was mistaken or the stars were far more distant than had previously been thought, so distant that existing instrumentation was insufficiently sensitive to detect this parallax. TYCHO BRAHE (1546–1601) was to carry pre-telescopic instrumentation to near its limits of accuracy,

and he estimated that his failure to detect annual parallax meant that it would have to be less than 1 arcmin and so—if Copernicus was right—the stars would be at least 700 times further than Saturn; this being so, even a third-magnitude star would have a volume 200 times that of the Sun. To have a universe at whose center was a solar system consisting of relatively tiny bodies, surrounded by an enormous and totally empty space before one came to stars of colossal size at its periphery, made no sense. Tycho's own geoheliocentric system, by contrast, retained Copernicus's relative geometry for the planets and the ancient value for solar parallax. It located the stars at a mere 14 000 Earth radii, and he estimated their volumes at between 68 Earth volumes for a bright star and 1/3 for a faint one.

In 1610 GALILEO (1564–1642) turned the telescope into an astronomical tool, although it was to be some decades before measuring instruments were supplied with telescopic sights. KEPLER's third law made it possible for the relative distances of planets from the Sun to be determined, in astronomical units. If therefore a planetary distance could be measured directly by triangulation, the astronomical unit could be calculated. It was Kepler himself who suggested this approach, using Mars, Mercury and Venus as targets. Tycho had attempted to measure the parallax of Mars, but Kepler's analysis of these data suggested a parallax no greater than 4 arcmin, which would reduce solar parallax to 2 arcmin. Taking into account corrections for refraction, Kepler later reduced this figure by half (see KEPLER'S LAWS).

The possibility that planets might be seen to TRANSIT across the face of the Sun had been recognized since Ptolemy's time, but was only now taken seriously. Kepler, whose own interest was primarily in planetary apparent diameters (as he believed planetary volumes were proportional to their distances from the Sun), correctly calculated that both Mercury and Venus would transit in 1631, on dates separated by 1 month. In the event Venus was not observed as it had already set for European locations, but three astronomers managed to obtain observations of Mercury. One successful observer, PIERRE GASSENDI (1592–1655), was surprised to find Mercury's image so small, much smaller than Kepler and others had expected. This fuelled the debate over planetary sizes and their relationship to distance, but contributed nothing to the measurement of parallax.

JEREMIAH HORROCKS (1618–1641), although a believer in Kepler's elliptical orbits, realized that planetary distances and sizes based on harmonies were incompatible with Gassendi's observation. In recomputing Venus's orbit, Horrocks discovered that it would transit the Sun in 1639. His observations showed a disk of about 1 arcmin. By invoking a dubious proportionality argument, Horrocks claimed that, as seen from the Sun, all planetary disks (including the Earth's) would appear to have an apparent diameter of 28 arcsec. This, he said, implied a solar parallax of 14 or 15 arcsec, which increased the Sun's distance enormously.

Horrocks's writings did not appear until many years after his death, and so had little impact, but several of his contemporaries were also of the opinion that the traditional value for the solar parallax was too large. G-B RICCIOLI (1598–1671), whose *Almagestum novum* of 1651 was the last major geocentric work, provided better observational data on planetary diameters and refraction, and a smaller solar parallax. However, Riccioli and some of his correspondents were still trying to build a distance scale observing lunar dichotomy. Better telescopic observations were required, and these came only with the invention of the micrometer. Although discovered accidently in England around 1640, it was not generally known until the 1660s. CHRISTIAAN HUYGENS (1629–1695) employed a crude micrometer to improve on the observations of his predecessors, and the instrument was further developed by Adrien Auzout (1622–1691), Pierre Petit (*ca* 1596–1677) and others. JOHN FLAMSTEED (1646–1719), the first Astronomer Royal, used the screw micrometer to good effect.

Now armed with telescopes superior in their ability to measure small angles, astronomers could attack planetary parallaxes anew. G-D CASSINI (1625–1712), when professor in Bologna, became interested in the question of how one finds the Sun's position while correcting for both parallax and refraction. If the solar parallax were quite small, then refraction at various altitudes above the horizon should be fixed throughout the year, but if parallax were larger, then one required variable refraction to account for the observations. This had been a serious issue for Tycho who, through assuming a solar parallax of 3 arcmin, required several different refraction tables, although he thought refraction negligible at altitudes above 45°. When Cassini arrived in Paris in 1669, members of the Académie Royale des Sciences debated this issue keenly. Observations in the tropics, when compared with those in Europe, might be decisive. As Mars was to be in a favorable opposition in 1672, Cassini urged an expedition to the colony at Cayenne, close to the equator. Jean Richer (died 1696) was dispatched, while Cassini made observations in Paris.

The results from Cayenne, while showing that refraction correction does indeed require only a single table, could not provide a parallax value that was unequivocal. Cassini found several values for Mars' parallax around 24 arcsec. Flamsteed, in England, was able to make a single observation with a micrometer later that year; although giving several versions of his results, by 1673 he claimed a horizontal parallax for Mars of about 25 arcsec, which implied a solar parallax of 10 arcsec. Instrumental errors were such that one could not rely on these measurements and the computed value for solar parallax, but it was now evident that solar parallax was truly small, less than 15 arcsec.

Transits of Venus and solar parallax

During the next half-century, English, French and Italian astronomers measured Mars' parallax at oppositions, obtaining solar parallax values ranging from 9 to 15 arcsec.

EDMOND HALLEY (1656–1742) dismissed observations of Mars as unreliable and argued for making careful measurements of a transit of Venus. He had himself observed a transit of Mercury from St Helena in 1677, but, on comparing his results with the single European observation, obtained a solar parallax of 45 arcsec, clearly too large. After careful consideration of Venus's orbit, Halley was able to calculate the dates of future transits of both Mercury and Venus, and these he announced in the *Philosophical Transactions* in 1691. The next pair of Venus transits would occur in June of both 1761 and 1769; another pair would follow in December of both 1874 and 1882. A second paper by Halley, published in 1716, laid out the method for observation, with suggestions of locations where the transit might be observed in 1761. Observers should time the transit from ingress on the Sun's limb to egress. One's geographic location determined where Venus's path would lie on the Sun's face and how long the transit would take.

Halley's younger French contemporary, J-N DELISLE (1688–1768), championed the transit method and proposed an alternative technique for observers who were not in a position to time the entire transit: if one could measure accurately the time of either ingress or egress, one could compare results with another observer so long as the longitudes of both locations were known accurately. For the same event, the time difference between two stations was related to the length of Venus's path across the Sun.

Delisle also pressed his contemporaries to measure the transit of Mercury which occurred in 1753. The results were disappointing, but the practice was valuable. In the run-up to the 1761 transit of Venus, the French worked to improve orbital calculations, with Delisle publishing a map and times a year before the event. Both the French and the British despatched expeditions overseas but most observations were taken in Europe, in a number of countries. With such a wide variety of observers and their differing experience, the results were equivocal, with estimates of the solar parallax ranging from 8 to nearly 11 arcsec.

With improved planning and support, the 1769 transit was even better observed, with some 77 stations involved world-wide. Again, results varied, but not so widely as in 1761. Part of the problem was lack of precise longitudes for distant stations. Atmospheric seeing, the quality of telescopes and observers' experience were also important factors. Furthermore, it was very difficult to determine the precise moment of ingress or egress, because observers noted a luminous ring around Venus and because of the 'black-drop effect', where a small, dark link seemed to join Venus's outline with the Sun's limb momentarily before or after contact. Nevertheless, Delisle's value of 8.6 arcsec was widely accepted, although during the following century, with the emergence of better statistical methods and advances in celestial mechanics, the value was revised upwards slightly.

A second pair of transits followed in 1874 and 1882 and were the focus of major international efforts with better instrumentation, which now included photography. However, observational teams arrived at a range of values between 8.76 and 8.85 arcsec, a discrepancy equivalent to about 2 million kilometers. Armed with data from four transits and revised longitudes for observing stations, SIMON NEWCOMB (1835–1909) calculated several values for solar parallax, ranging between 8.79 and 8.85 arcsec. After further work on the speed of light with A A MICHELSON (1853–1931), Newcomb settled on 8.80 arcsec. In the late 1870s, DAVID GILL (1843–1914) made another attempt at Mars' parallax at opposition, obtaining a value for solar parallax of 8.78 arcsec, close to Newcomb's early estimate.

Even before the 1874 transit of Venus, J G GALLE (1812–1910) suggested that minor planets might be better targets, as they showed no visible disk. Measurements of three in the late 1880s allowed Gill to obtain a value of 8.80 arcsec, which within limits of error almost matched the revised value provided by Newcomb. In 1898, it was calculated that a newly discovered minor planet, EROS, would have a perihelion distance of only 0.27 astronomical units from Earth at its opposition in 1900. However, even then, visual and photographic observations yielded two different values for the solar parallax, 8.806 ± 0.004 and 8.807 ± 0.003 arcsec, so placing the Sun at more than 140 million kilometers from Earth at its mean distance. These values would stand for another 40 yr, until observations of Eros's opposition in 1930 were reduced and published.

Stellar distances

When Galileo became converted to Copernicanism, he realized that the detection of annual parallax was a priority. Assuming the stars lay at differing distances and that the brightest were the nearest, he suggested that examination of DOUBLE STARS might avoid some of the practical difficulties involved in observations spread over many months and being made with instruments liable to warp with the passage of the seasons. If the fainter star of a double was much more distant than its brighter partner, then the fainter star could be regarded as a quasi-fixed reference point provided by a helpful Nature, and the astronomer might observe the motion of the brighter star relative to the fainter. However, as so often he contented himself with offering the suggestion for others to implement.

After Kepler taught astronomers to think dynamically and to view the planetary system as composed of small bodies in orbit about a massive Sun, the detection of annual parallax ceased to be a test of Copernicus's hypothesis and became instead the preferred method of determining the distances of the stars. The problems were practical, and not least among these was refraction, whose effects were poorly understood. ROBERT HOOKE (1635–1703) sought to avoid this difficulty by observations of the star GAMMA DRACONIS, which passed directly overhead his lodgings in London. To ensure that his instrumentation was not warped by the passage of the seasons, Hooke devised a zenith telescope which he incorporated into the fabric of his house. However, he made only four observations of

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the star, and other astronomers found his claim to have detected annual parallax unconvincing.

The same technique was applied with much greater care in the 1720s by an amateur, SAMUEL MOLYNEUX (1689–1728), and his friend JAMES BRADLEY (1693–1762), a future Astronomer Royal. Molyneux commissioned a zenith telescope from the maker George Graham; with it, he and Bradley found that there was indeed an annual movement in gamma Draconis, but that it was 3 months out of phase with the expected annual parallax. Bradley therefore commissioned another zenith telescope, with a wider field of view, and this enabled him to establish the pattern of this annual movement in a number of stars. Eventually he realized that the cause lay in the aberration of light, the influence of the Earth's velocity on the direction from which starlight reaches the observer. It was proof of the motion of the Earth, but not the expected one. Bradley estimated from his failure to detect annual parallax that the distances of the stars must be at least 400 000 astronomical units.

Meanwhile other investigators were attempting to estimate stellar distances on the assumption that the stars were physically similar, so that the apparent brightness of a star was inversely proportional to the square of its distance from the observer. The problem was, how in practice to make the comparison between the apparent brightness of the Sun and, say, SIRIUS. Huygens attempted to do this by making a hole in a screen, of a size such that the fraction of the solar surface visible through the hole was equal in brightness to Sirius. From this he estimated that Sirius lay at 27 664 astronomical units.

A better method was proposed by JAMES GREGORY (1638–1675) in 1668. Assuming a knowledge of the dimensions of the solar system, Gregory replaced Sirius by a planet of equal brightness, and then calculated the ratio of the light that came directly from the Sun to the light that came from the Sun via the planet. Isaac NEWTON (1642–1727) repeated the calculation with better values for the distances within the solar system, and concluded that Sirius lay at about one million astronomical units. However, his estimate was known only to intimates until its posthumous publication, which occurred only a few months before Bradley's announcement in 1729 of the aberration of light and its implications. These two results—Newton's estimate of an actual distance for Sirius of one million astronomical units on the assumption of physical equality among the stars and Bradley's estimate of a minimum stellar distance of 400 000 astronomical units—established the scale of the stellar universe, and alerted astronomers to the exquisite delicacy involved in the measurement of annual parallax.

There was an understandable loss of nerve, and only at the beginning of the 19th century did attempts to measure annual parallax resume. Telescopes had improved in quality, and it was becoming realized that large proper motion might be a better clue to nearness than apparent brightness. In particular, the discovery that 61 CYGNI had a proper motion of no less than 5 arcsec per annum suggested that this star might be among the nearest.

The early decades of the 19th century saw a rash of mistaken claims to the detection of annual parallax, and sceptical astronomers would need convincing evidence before believing any future claim. Such evidence was provided by FRIEDRICH WILHELM BESSEL (1784–1864) of Königsberg, where there was a fine 16 cm heliometer by Joseph Fraunhofer. In 1837 and 1838 he observed 61 Cygni an astonishing 16 times or more every clear night, and at the end of 1838 he announced the star had a parallax of about 1/3 of a second of arc. What carried conviction was the match between theory and the pattern of Bessel's observations.

Bessel had been encouraged by the preliminary results of Friedrich Georg WILHELM STRUVE (1793–1864) of Dorpat Observatory in Russia, who had been observing VEGA with a Fraunhofer refractor of 24 cm, the largest in the world. Vega was bright and had a large proper motion. Struve observed the star from 1835 and derived a parallax of 1/8 of a second of arc, although he later doubled this value. A third determination was announced in January 1839 by THOMAS HENDERSON (1798–1844) following his return from the Cape of Good Hope, where the stars he had observed included ALPHA CENTAURI. This star was bright, was a double with wide angular separation and had a large proper motion, all recognized criteria for nearness. On reducing his observations Henderson derived a parallax of over 1 second of arc.

For the remainder of the 19th century, measurements of annual parallax proved difficult and the results were often contradictory, even after the invention of photography. Furthermore, measurements of distances beyond the nearest stars were hardly to be expected, given that as late as 1900 the very existence of other galaxies was thought unlikely. However, William Herschel (1738–1822) had pioneered methods that would bear fruit in the 20th century, even if he had limited impact on his contemporaries and immediate successors (see HERSCHEL FAMILY). In 1785 he had published a diagram of a cross-section of the Galaxy, using the distance of Sirius as a yardstick. He had assumed that within the Galaxy the stars were distributed uniformly, and that his telescope could penetrate to the borders in all directions, so that the number of stars visible in any field of view was an index of the distance to the border of the Galaxy in that direction. Both assumptions he later abandoned, but his diagram had illustrated the potential power of hypotheses of uniformity when combined with stellar statistics. It was after reasoning along similar lines that he told the poet Thomas Campbell in 1813, 'I have observed stars of which the light, it can be proved, must take two million years to reach the earth' (Lubbock C A 1933 *The Herschel Chronicle* (Cambridge: Cambridge University Press) p 336

Distribution of Galaxies, Clusters, and Superclusters

The distribution of matter in space is the key to understanding the past, present, and future of the universe. If the average mass density on the largest scales exceeds a critical level, then the expansion of the universe will eventually cease and reverse, ultimately ending in a 'Big Crunch'. Conversely, if the mean mass density in the universe is less than this critical value, the expansion of space will continue without end. The distribution of matter also reveals much about the cosmic history of the universe: matter was very smoothly distributed shortly after the Big Bang but is much less so now. When observations of how galaxies and CLUSTERS OF GALAXIES are spread throughout space are combined with observations of their spectroscopic and morphological properties, astrophysicists can place important constraints on how these systems formed, evolved, and, ultimately, elucidate the nature of the growth of structure in the universe. In particular, the relationship between the distribution of luminous matter (e.g., hot gas, stars, galaxies) and non-luminous matter (e.g., non-baryonic particles) is determined by the thermal properties of the non-baryonic 'dark' matter, the history of star formation, gravity, and the cosmological model. Hence, accurate predictions for the spatial distributions of galaxies and clusters as functions of time are fundamental requirements for any viable theory of how structure in the universe formed and evolves. Studying the distribution of galaxies and clusters over a range of distances and epochs has, consequently, been an area of much active research over the past 20 years. While there is still much that is unknown about the underlying mass distribution in the universe, substantial progress has been made owing to breakthroughs in astronomical instrumentation and detector technology, numerical simulation software and high-speed computer processors, and particle physics. What we do know is that the distributions of galaxies and clusters show a remarkable degree of inhomogeneity over distances spanning at least 150 megaparsecs (Mpc) and that the clustering properties of galaxies appear to depend on both the local environment the galaxy resides in and on the intrinsic properties of the galaxy. The precise nature of the DARK MATTER and the role of gas hydrodynamics (e.g., STAR FORMATION) in the evolution of structure, however, presently remain unsolved problems in astrophysics.

The cosmological principle, dark matter, and the clustering hierarchy

A guiding principle of cosmology has been that if one looks out to large enough distances, then the universe should be homogeneous and isotropic. This assumption is often referred to as the 'COSMOLOGICAL PRINCIPLE'. By isotropic, we mean that the global properties of the universe (and, therefore, the galaxy distribution) are not dependent the viewing direction. By homogeneous, we mean that observers in different parts of the universe will record the same basic picture of the universe at a given cosmic epoch. The gist of the cosmological principle is that there are no preferred directions or locations in the universe. Present observations suggest that the cosmological principle is valid but only on distance scales in excess of 150 Mpc or so. On smaller scales, we do see spatial variations in galaxy properties (and possibly even in certain cosmological parameters) which are presumably tied to substantial fluctuations in the underlying distribution of matter in space.

Early maps of the galaxy distribution on large scales, generated prior to the 1980s, were two dimensional—reproducing the distribution of galaxies on the plane of the sky. The third dimension, distance from our Galaxy, was only available for a small fraction of those galaxies. Nonetheless, these maps showed the distribution of galaxies to be highly non-random: when one galaxy is found, the likelihood of finding a nearby companion galaxy is significantly higher than Poisson statistics would predict.

Clustering in the universe is detected on many different scales. Our Milky Way Galaxy is a member of a group (named the LOCAL GROUP) of 24 galaxies spread over a region about 1 Mpc in radius. The Local Group contains a total mass in the range 3×10^{12} to 10^{13} solar masses. Groups like this are relatively common: on average, there is approximately one group for each 1800 cubic Mpc volume. Clusters of galaxies are approximately comparable in size, spanning 1–5 Mpc, but are considerably more massive and rarer than galaxy groups (figure 1). Clusters contain hundreds of galaxies in their central regions. The total cluster mass is usually at least 10^{14} solar masses and the richest systems can be 50 times more massive than that. The mass density within a cluster is typically at least 100 times the universal closure density[1]. Clusters of galaxies are the largest systems known to have reached dynamic equilibrium, a state in which the cluster's gravitational potential energy is twice its internal kinetic energy. Gravitationally bound structures may exist on larger scales still. Although quite rare, clusters of clusters (known as SUPERCLUSTERS) have been detected. These systems can contain in excess of 10^{16} solar masses, including up to 10 individual galaxy clusters spread across regions 10–30 Mpc in extent. Some superclusters are suspected of being bound systems but it is highly

[1] The universal closure density is 1.88×10^{-29} grams per cubic centimeter. This is the minimum mean mass density required to eventually halt the present expansion of the universe.

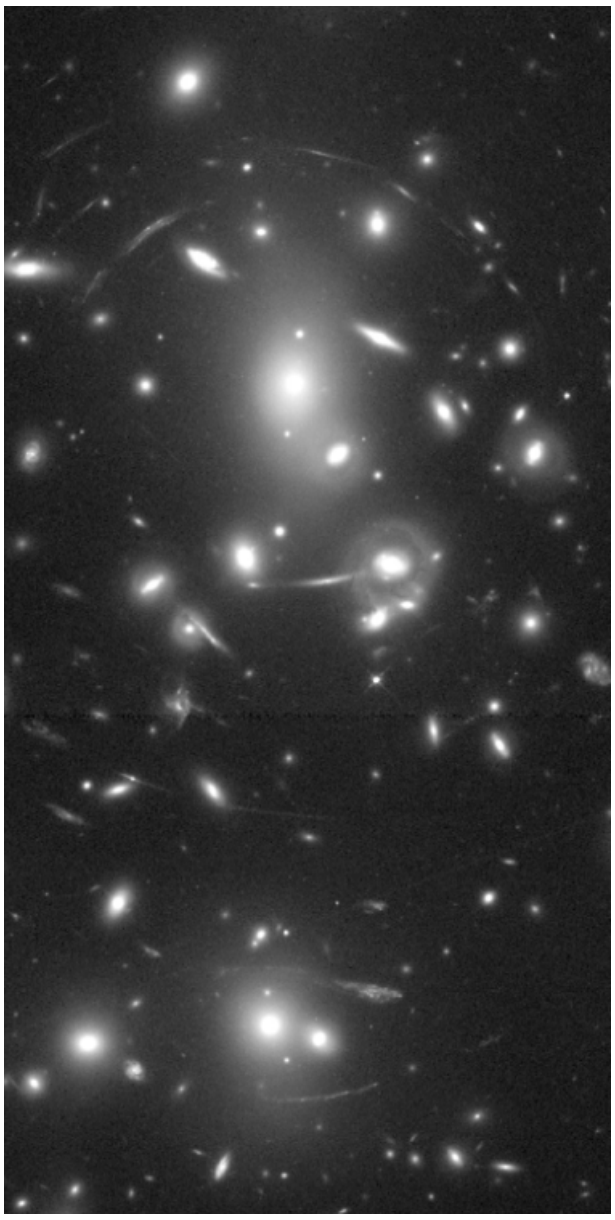

Figure 1. The galaxy cluster Abell 2218 as seen by the Hubble Space Telescope. The field of view spans a distance of about 415 kpc. The curved, faint galaxies are actually distant galaxies lying well beyond the cluster whose appearances have been distorted by the effect of the cluster's mass on the curvature of space. Such distortion, known as gravitational lensing, is one way the mass of a cluster can be estimated.

unlikely they have had sufficient time to reach dynamical equilibrium.

Structure on scales in excess of 100 Mpc was not discovered until wide-area, three-dimensional galaxy surveys were first undertaken in the early 1980s. Three-dimensional surveys are essential for discovering the true nature of the galaxy, cluster, and supercluster distributions because projection effects hide substantial

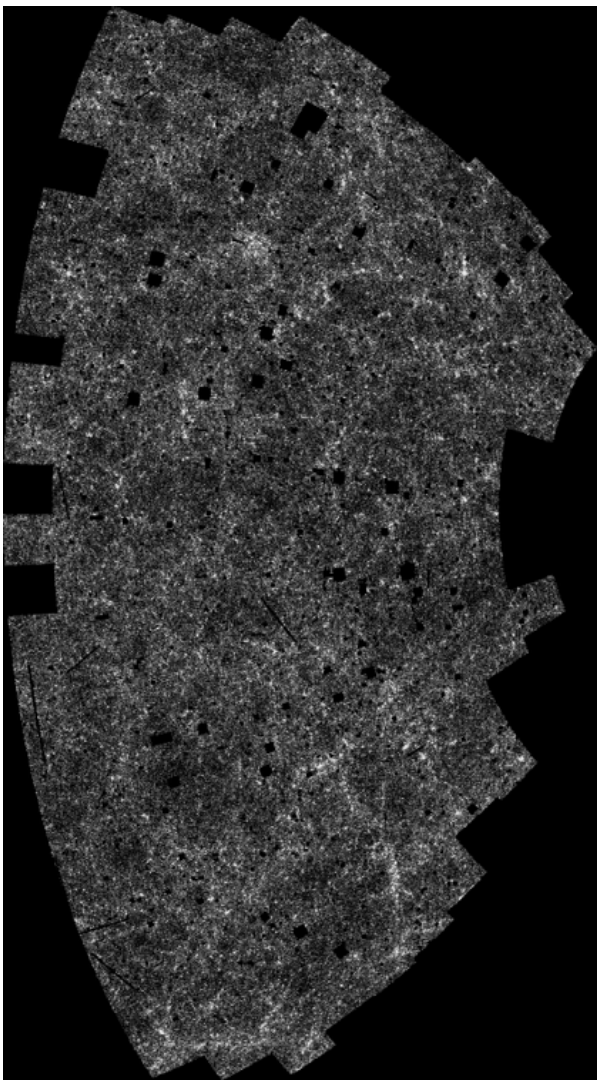

Figure 2. A map derived from digitized photographic sky survey plates showing the angular distribution of over 2 million galaxies in the southern galactic hemisphere. Blank regions in the map were skipped due to the presence of very bright stars.

structures in two-dimensional maps like that in figure 2. Indeed, an amazing bubble-like network of voids and sheets of galaxies and clusters, extending for hundreds of Mpc, is revealed in these spatial surveys.

The clustering patterns that we see in the universe, from galactic scales and up, are believed to be governed by the gravitational potential of ubiquitous dark matter. The galaxies, which comprise less than 5% of all the matter in the universe, are simply tracers of the dark matter distribution. This remarkable realization is based on observations which infer the total mass in galaxies and in clusters of galaxies from the distribution of orbital velocities of the material inside these systems. The dynamical mass estimates derived in this way are typically 5–10 times larger than the masses estimated by summing up the luminous components (e.g., stars in the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

case of galaxies; galaxies and hot gas in the case of clusters). The implication is that most of the matter in the universe has not yet been directly detected by conventional astronomical instrumentation.

The nature of this dark matter is still not well understood. The hypothesis that dark matter consists solely of BARYONS (e.g., neutral gas, dilute plasma, massive planets, white dwarfs, neutron stars, and black holes) appears to be in conflict with observations of hot gas in clusters of galaxies (the gas comprises only about 10–20% of the total cluster mass), the tendency for dying stars to eject a substantial fraction of their mass back into interstellar space (and, hence, locking baryonic matter in stellar remnants is a very inefficient process), and limits on the number of massive planets, brown dwarfs, and very low mass stars from both gravitational micro-lensing surveys and deep Hubble Space Telescope images (the space density of such objects is too low to account for a significant fraction of the inferred total mass density in the universe).

The spatial distribution of galaxies and clusters can help constrain the nature of the dark matter because dramatically different configurations are predicted depending, for example, on whether or not the dark matter particles are highly relativistic (dubbed hot and cold dark matter, respectively). Candidates for non-baryonic dark matter include neutrinos, axions, and the weakly interacting massive particles predicted by supersymmetry models (photinos, higgsinos, zinos, and solar cosmions). Programs to detect the more exotic of these cosmological non-baryonic particles are underway.

Voids, sheets, filaments, and spikes

The frothy spatial distribution of about 10 000 galaxies in two nearly opposing directions is shown in figure 3. The data were obtained at observatories located in Arizona and Chile. In this figure, known as a cone diagram, each galaxy's position is shown as a point. Our own galaxy is located at the point where the wedges meet. The distance represented by the length of each wedge is about 120 Mpc. Several striking features are evident in this galaxy map (none of which were predicted by theory prior to the observations): large regions of very low galaxy density, somewhat misleadingly referred to as voids, extend for tens of Mpc. The voids are surrounded by a sheet-like network of galaxies often extending for several hundred Mpc. Indeed, one such coherent feature can be seen in figure 3 crossing from the mid-region of the northern cone diagram into and across the southern cone diagram. This feature has been dubbed the 'GREAT WALL'.

Clusters of galaxies can also be seen in the map as highly elongated clumps oriented towards the center of the diagram. This elongation is an artifact of the large, orbital velocities of galaxies about the cluster centers which can often approach 1000 km s^{-1}. These orbital velocities distort the spatial positions determined from the redshift measurements and result in the elongated appearance of clusters in such diagrams. If we could observe the cluster galaxies using a map based on distances not dependent on the REDSHIFT, such elongation would vanish.

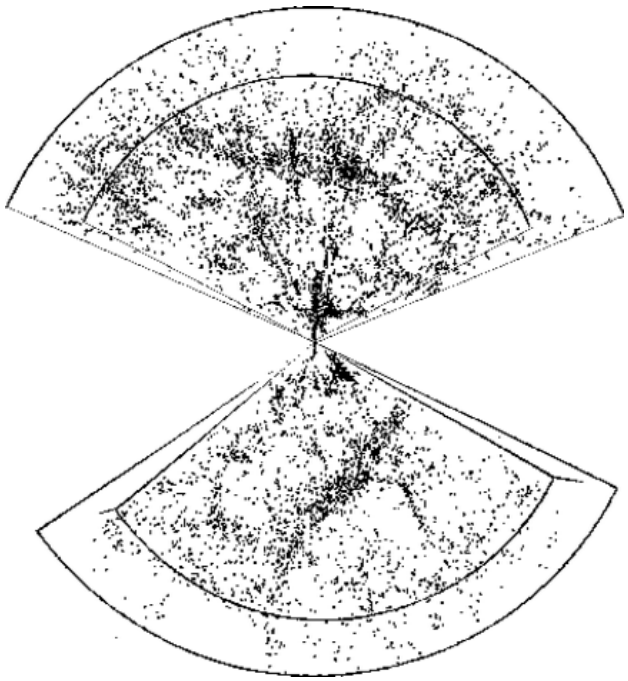

Figure 3. The spatial distribution of approximately 10 000 galaxies extending out to a distance of 120 Mpc. Galaxies from a small portion of the northern galactic hemisphere are shown in the upper cone diagram and those from a comparable region in the southern galactic hemisphere are shown in the lower cone diagram. These data are from a large redshift survey coordinated by the Center for Astrophysics at Harvard University.

The structures in this map are clearly comparable with the depth of the survey and, thus, wider and deeper surveys were undertaken in the 1990s to assess just how large the largest structures in the universe are (see GALAXY REDSHIFT SURVEYS). One technological development which made very large redshift surveys feasible was the multi-object spectrograph (MOS). The 10 000 redshifts above were measured one at a time on telescopes which had narrow fields of view ((1/7)th the area subtended by the full Moon). Multi-object spectrographs today allow up to 600 redshifts to be measured simultaneously from galaxies spread over an area of a few square degrees (roughly 15 times the area subtended by the full Moon).

One of the first large MOS surveys to be completed, known as the Las Campanas Redshift Survey (LCRS), measured about 24 000 redshifts in two directions 132° apart. The distribution of galaxies from this survey is shown in figure 4. The depth of the LCRS

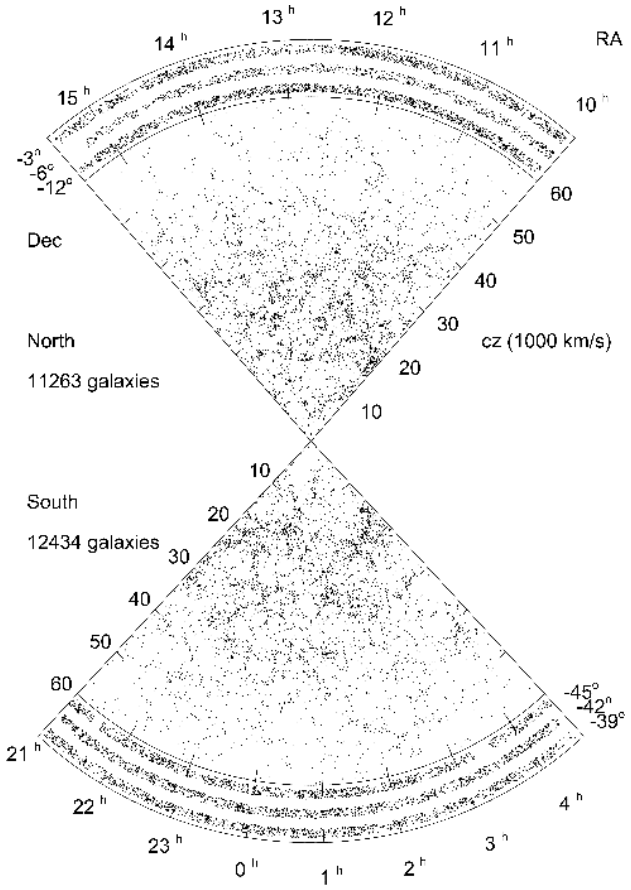

Figure 4. The spatial distribution of approximately 24 000 galaxies extending out to a distance of 600 Mpc. These are the results from the Las Campanas Redshift Survey conducted by an international team of astronomers using a Chilean telescope equipped with a multi-object spectrograph. The 3 bands going across the top and bottom show the projected distribution of the galaxies on the sky. Although the depth of this survey is substantial, it only subtends 0.3% of the entire sky.

was nearly 5 times greater than that in figure 3. Yet the structures found were comparable in size suggesting that perhaps there are no substantial inhomogeneities much larger than 120 Mpc. However, the LCRS only includes distances for a fraction of all the galaxies in this part of the sky due to time and telescope constraints. As a consequence, the structure in the LCRS map is not as clearly delineated as that in a survey which completely samples the galaxy distribution, such as the one in figure 3. Any conclusions regarding the existence of structures on scales larger than 120 Mpc or so must therefore be tempered by the fact that the survey has only done a partial sampling of the galaxy and cluster distribution.

The results of the most extensive redshift survey of clusters of galaxies is shown in figure 5. The radius of the survey is 240 Mpc and includes about 50% of the ~1000 clusters actually residing in this volume.

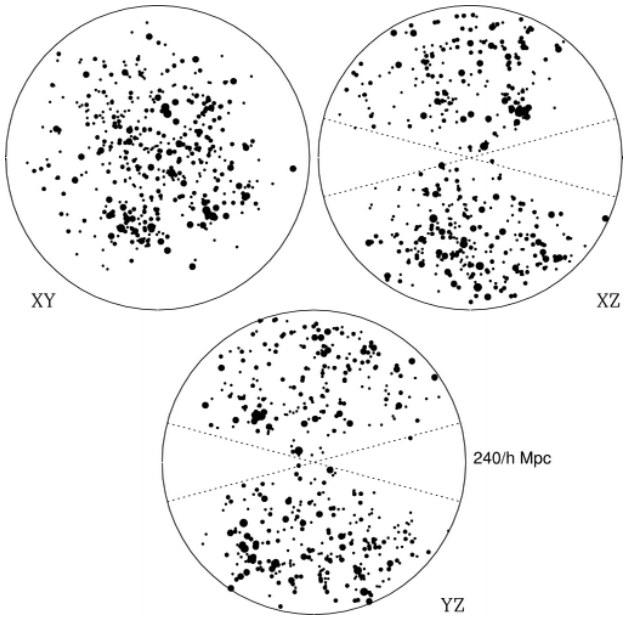

Figure 5. Three views of the spatial distribution of the richest ~480 clusters within a radius of 240 Mpc, centered on our Galaxy. Each dot represents a cluster and the dot size is proportional to the number of bright galaxies in the central region of the cluster. The empty wedges in the XZ and YZ projections are due to the blockage by the disk of our Galaxy.

Quantifying clustering

The constraints that the above surveys place on theories of structure formation and dark matter models come from a variety of statistical quantities which measure the degree to which the galaxy and cluster distributions differ from a purely random configuration. One of the most widely used of these statistics is the two-point correlation function, $\xi(r)$. The two-point correlation function measures the probability of finding one galaxy separated by a distance r from another galaxy. The observations above reveal that $\xi(r)$ is well represented by a power law of the form

$$\xi(r) = \left(\frac{r_0}{r}\right)^{\gamma} \quad (1)$$

where r_0 is known as the correlation length. The correlation length is the distance scale at which there are twice as many pairs of objects than expected if the distribution of objects were completely random. For galaxies, the best-fit parameters for $\xi(r)$ are $r_0 = 5.5\pm1$ Mpc and $\gamma = 1.8\pm0.05$. If the distribution of galaxies were random, one would expect $\xi(r) = 0$ at all scales. The constraints on $\xi(r)$ mirror the visual impression given by the redshift surveys—the galaxy distribution is strongly clustered, not random. Remarkably, the correlation function of clusters of galaxies has a slope nearly identical to that for galaxies ($\gamma = 1.9\pm0.3$) but the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001

correlation length is significantly larger, $r_0 = 20\pm8$ Mpc. The agreement between the shape of $\xi(r)$ for galaxies and clusters suggests that these two rather different types of stellar systems trace the same underlying mass distribution. An additional constraint from the redshift surveys of galaxies and clusters is that the power-law representation of $\xi(r)$ appears to be valid on scales up to at least 40 Mpc and perhaps as high as 60 Mpc.

The correlation function parameters above are mean values for large samples of galaxies and clusters. The values are not universal, however. There is a highly significant dependence of the correlation length on the luminosity of the galaxies being studied and on their morphology. For example, it has recently been established that the correlation function of the most optically luminous galaxies ($L_{opt} \geq 5 \times 10^{43}$ erg s^{-1}) have correlation lengths of ~16±2 Mpc, approaching that of clusters of galaxies, whereas the intrinsically faintest galaxies have correlation lengths as low as 4 Mpc. It has also been established that the likelihood of finding a neighbor galaxy within 1 Mpc from an elliptical is about twice as high as that for finding a companion within the same volume from a spiral galaxy. Thus, although all the distribution of all galaxies is determined by the underlying matter distribution, elliptical galaxies and/or luminous galaxies appear to be more efficient tracers of regions in space with the highest densities. The cluster correlation function parameters also appear to depend weakly on the cluster's x-ray luminosity: the most luminous x-ray clusters ($L_X \geq 1.4 \times 10^{44}$ erg s^{-1}) have $r_0 \approx$ 35±15 Mpc, compared to $r_0 \approx 15\pm4$ for the least rich (and least x-ray luminous) systems.

The power spectrum, $P(k)$, is the Fourier transform of $\xi(r)$ and provides a complementary but important constraint on the clustering properties of galaxies and clusters: broad features in the correlation function are narrow in Fourier space and vice versa (see CORRELATION FUNCTION AND POWER SPECTRA IN COSMOLOGY). An analysis of the distribution of galaxies in the LCRS revealed there is a significant 'spike' in the power spectrum on scales near 100 Mpc. Deeper redshift surveys, known as 'pencil beam' surveys because they cover very small solid angles but probe great distances, also have detected excess clustering signatures on scales of up to 130 Mpc. Indeed, the results from the first pencil beam surveys showed there appeared to be quasi-periodic spikes in the radial distribution of galaxies, occurring every 120–130 Mpc. These features are surprising since it is not understood why there should be such a preferred size scale. One interpretation is that structures on large scales, like the network of walls and voids seen in the wide area redshift surveys, have characteristic sizes. But what determines these characteristic scales? Some of this excess power could be the lingering effects of the properties of the plasma that existed in the very early universe. But at present we do not really understand the origins of these remarkable features in the galaxy distribution. Nonetheless, the global shape of the galaxy and cluster power spectra are similar, suggesting again that clusters and galaxies are tracing similar perturbations in the matter distribution. The amplitude of $P(k)$ for the richest clusters is, on average, a factor of ~2–3 higher than that for poorer clusters, consistent with differences seen in their respective $\xi(r)$. In turn, the rich cluster $P(k)$ amplitude is about 12–16 times higher than that derived for galaxies in the LCRS.

'Biasing'

The above results demonstrate that not all extragalactic objects trace the underlying mass distribution in the same way. Indeed, this conclusion represents a substantially new paradigm in cosmology. Prior to the early 1980s it had usually been assumed that a one-to-one relation existed between fluctuations in the distribution of galaxies and fluctuations in the distribution of mass. We now realize that not only is the relationship not a direct one but it probably is not even a linear one and may depend on time and size scale, as well. Galaxies and clusters are thus deemed 'biased' tracers of the matter distribution and much research is now in progress to understand the physical mechanisms which can account for this more complex relation between the galaxy, cluster, and matter distributions.

The dependence of the clustering properties, such as the correlation length, on the mass of the system have been explained in terms of the statistics of 'rare peaks' in a distribution. Fluctuations in the density of mass in the universe occur on many scales. Superposed on the largest fluctuations are smaller ones. If galaxies and clusters of galaxies form at sites which achieve some minimum density enhancement, then there will be a preference for the most massive and most luminous objects to form at those sites which already have elevated mass density levels by virtue of sitting atop the peak of a larger scale fluctuation. The highest density peaks in the mass distribution, however, occur less frequently—one has to search a larger volume to find a large density peak than a small peak. It has been proposed that a universal relation can be made between the mean separation between objects, d_i, and their correlation length, r_0, of the form

$$r_0 = (0.3 \pm 0.1) d_i \tag{2}$$

implying that objects with larger separations (which tend to be more massive systems) will exhibit stronger clustering[2]. Does the trend between clustering strength and mass extend to superclusters? The answer is unclear because there are too few superclusters known at present to perform robust computations. Surveys initiated in

[2] The mean interobject separation is defined as $d_I = (n_i)^{-1/3}$ where n_i is the mean space density of the objects.

1998 may yield enough additional superclusters to address this question.

Although early versions of structure formation theory based upon a universe dominated by cold dark matter (CDM) did predict a trend towards higher correlation lengths as the galaxy and cluster mass increased, these same models did not come close to predicting the actual observations in which the richest clusters are 10–20 times more strongly clustered than are galaxies. The resolution of this discrepancy was to postulate that galaxies and clusters are biased tracers of the mass. These biased CDM models are more successful at reproducing the actual galaxy distribution, but there remain other significant observations with which the models do not agree very well. This is probably because either the dark matter properties assumed are not accurate and/or the specific biasing model is not accurate.

Statistics like $\xi(r)$ and $P(k)$ are not sufficient to unambiguously describe the galaxy and cluster distributions. Distributions that appear dramatically different to the eye can often have similar two-point correlation functions. This is because the eye is sensitive to high-order moments of the distribution (such as 'wall'-like bands of galaxies surrounding large, underdense volumes). Statistics which measure the high-order moments of the distributions thus provide superior discrimination between cosmological models as well as some of the best constraints on the degree of biasing and, thus, on the reliability of galaxies and clusters as tracers of the mass. Current constraints on the higher moments (orders 3–6) of the galaxy and cluster distributions suggest that while galaxies and clusters are sampling the same underlying matter distribution the biasing between them is non-linear.

Cosmic flows

The above observations demonstrate both the power and limitations of mapping structure with redshift surveys. While such surveys succeed in revealing extensive and intricate structures on many scales, the physical interpretation of the structure is complicated by the fact that the tracers of the structure are biased. However, there is a complementary approach to mapping structure which takes advantage of the fact that all the matter in the universe is subject to its own mutual gravitational force. Inhomogeneities in the mass distribution can induce motions of galaxies and clusters (dubbed 'peculiar' velocity by astronomers) which are unrelated to the expansion of space. On scales larger than about 10 Mpc, a three-dimensional map of these motions can be used to infer the masses and probable locations of the responsible structures because the induced velocities are linearly proportional to the gradients in the gravitational field[3]. The beauty of such measurements is that they provide a more direct method for mapping the mass distribution and many of the concerns about biased tracers are moot. Peculiar velocity observations are, however, difficult to perform accurately.

The observational study of large-scale cosmic velocity fields began in 1976, with the discovery that the temperature of the COSMIC MICROWAVE BACKGROUND (CMB) is a few millidegrees warmer in one direction and equally cooler in the opposite direction. This signature was quickly interpreted as due to motion of our Galaxy relative to the CMB, motion that is assumed to be due to an imbalance in the gravitational tug of the various structures which surround our Galaxy. (If matter were uniformly distributed around us, the gravitational forces would cancel, on average, and no motion would be induced. However, as seen in the redshift surveys matter is very far from uniformly distributed.) Subsequent measurements of this anisotropy from the Cosmic Background Explorer (COBE) satellite have yielded a highly accurate measurements of this motion: 620 km s^{-1} towards the direction l = 270.8°, b = +29.1°, when measured with respect to the center of the Local Group. Since the CMB is the most distant reference frame possible (it originates at a redshift of ~1000, when the universe was only a few hundred thousand years old), it is quite reasonable to presume that the structures causing this motion are much closer.

In order to measure the peculiar velocity of an extragalactic object, one needs to know both its redshift and its distance. In this case, the distance must be determined *independently* from the redshift. This is because the observed redshift contains contributions from both the expansion of the universe and from any gravitationally induced velocity. The contribution solely from the expansion (referred to as the recession velocity) can be determined directly from the redshift-independent distance via HUBBLE'S LAW. The peculiar velocity is then the difference between the observed redshift and the recession velocity. There are presently at least seven independent methods which can be used to determine distances to galaxies and clusters, albeit not all methods work on all galaxy systems nor do they all yield the same measurement accuracy. However, the common principle in all of these methods is that there exists some observable quantity (other than redshift) that can be used to estimate the distance. In many of these methods, the distance is inferred by comparing an estimate of the object's intrinsic luminosity with its apparent (observed) luminosity.

[3] On scales less than 5 Mpc, the relationship between induced velocity and mass becomes highly nonlinear making reconstruction of the underlying structure from peculiar velocities extremely difficult.

Using such techniques, redshift-independent distances (and, hence, peculiar velocities) can be established for large samples of galaxies and clusters in different parts of the sky. From such datasets, the motions of galaxies can be charted and the presence of fluctuations in the matter distribution then inferred. The two largest galaxies in the Local Group, our Milky Way and the Andromeda galaxy, are separated from one another by about 700 kpc. Two massless particles sitting that far apart in our expanding universe would be traveling away from one another at more than 50 km s^{-1}. In fact, these two galaxies are moving towards one another at about 70 km s^{-1}. This observation has led to estimates of the combined mass of these two spiral galaxies. The entire Local Group itself is moving due, in part, to the gravitational pull of the VIRGO CLUSTER which lies about 16 Mpc away. But the Virgo cluster mass is sufficient to explain only about 40% of the CMB velocity. Additionally, the CMB velocity vector is misaligned with the position of the Virgo cluster by 47°. Additional structures at larger distances must, therefore, play a role.

One of the first peculiar velocity surveys to detect these structures was conducted in the mid-1980s using distances to over 300 elliptical galaxies. A startling result was found: a vast number of galaxies within a sphere nearly 100 Mpc in diameter appear to share a common motion towards a massive aggregate of matter. Such a motion is referred to as a 'bulk flow' and since so many galaxies participate in it, the aggregate was dubbed the 'Great Attractor'. The bulk flow vector was 600±104 km s^{-1} towards $l = 312°$, $b = 6°$ (angular error is ~±10º), close to the CMB velocity of 620 km s^{-1} but about 45º from its apex. Subsequent surveys indicate that the 'Great Attractor' is a moderately rich supercluster lying between 40–50 Mpc from our Galaxy. The Great Attractor itself may be participating in a bulk flow suggesting that the origin of the flow is due, in part, to structure on scales larger than 50 Mpc.

Do such bulk flows extend to scales of 100 Mpc or larger? If so, then the cosmological principle is not valid on scales even as large as 100 Mpc. With this key question as a driver, several groups set out to explore the velocity field on scales 4 times larger than the original 'Great Attractor' survey. Initial results from some of these surveys suggest there is evidence for bulk flows of 600–800 (±150–300) km s^{-1} which extend out to scales of 100 Mpc or more. The different surveys have not all yielded consistent directions for these flows, however. There is some evidence to suggest that these very large-scale flows point to within ±30º of the Shapley supercluster, a system with a mass of a few × 10^{16} solar masses located 150 Mpc from the Local Group and towards $l = 312°$, $b = 30°$. The results are controversial and this is presently a research area of much active observational work. One challenge of measuring bulk flows on such large-scales is that the signal is small and often must be extracted from noisy data. If very large-scale bulk flows turn out to be a reality, then present models for structure formation in the universe will require substantial revision (if not outright rejection).

The Hubble bubble?

Gravitational attraction towards massive structures is not the only means available for generating a large bulk flow, however. If the expansion of the universe were dependent on one's location, then flows could be a direct consequence. Another way to ask this question is: is the Hubble constant (H_0) really constant? The answer is no. A more accurate description of this term would be the Hubble parameter. The Hubble parameter does vary with cosmic age—the temporal dependence is a consequence of the deceleration of the expansion caused by the matter in the universe. The amplitude of the time dependence, however, only becomes significant when surveys span very large distances (and, hence, a large dynamic range in 'look-back' time). Variations in the value of H_0 as a function of location, however, are also possible if the fluctuations in the mass distribution are sufficiently large. The expansion of space within a large underdense region will proceed at a faster rate than that in a large overdense region. The size of the voids and walls seen in the galaxy distribution are, in principle, large enough to yield measurable variations in the Hubble parameter on scales of 100–200 Mpc. As figure 3 shows, the region of space surrounding our Galaxy is underdense relative to, for example, the 'Great Wall' structure which lies about 70–100 Mpc away. One possible explanation, then, for a large peculiar velocity on the scale of 100–200 Mpc is that our Galaxy resides in a region of space where the local expansion rate is faster than that on much larger scales. To date, the observational constraints on the spatial variation of the Hubble parameter are less than 5% on scales of 150 Mpc. Although small, this can still amount to a few hundred km s^{-1} and thus such effects may indeed be at work.

Future observations and outstanding problems

One key challenge posed by all these observations is to understand how the universe evolved from its highly homogeneous state shortly after creation to the present epoch where large inhomogeneities on scales of 100 Mpc, or more, are relatively common. The models which appear most consistent with the majority of the observations are those which call for a CDM-dominated open universe and/or an open universe with CDM plus some hot dark matter component such as neutrinos. The observations may also be consistent with a non-zero cosmological constant (Λ). If the large-amplitude, large-

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

scale bulk flows persist, however, some revisions to these models will be required.

While much progress has been made in mapping the structures in the universe, we still have a ways to go. At present, the fraction of the local universe for which we have reliable maps of the galaxy and cluster distributions is a mere 1%, akin to trying to infer the geography of the entire surface of the Earth from a map of the eastern half of the United States. Some fundamental astrophysical problems in the study of the distribution of galaxies, clusters, and superclusters still remain unsolved. Are there galaxian structures on scales beyond 300 Mpc? Are there bulk flows which indeed extend beyond 100 Mpc? Just how complex is the relationship between the galaxy distribution and the matter distribution? What structure existed when the universe was half or even one tenth its present age? What is the precise nature of the dark matter in the universe?

Given the limited amount of telescope time available to conduct surveys of the galaxy and cluster distributions, astronomers have had to balance the desire to cover large areas of the sky (and hence sample many nearby regions of space) and the desire to probe the galaxy distribution at great distances (to study the evolution of structure). Fortunately, as multi-object spectrographs improve and more large-aperture telescopes are constructed, including a few observatories solely dedicated to spectroscopic surveys, the trade off between area and depth is becoming less of an issue. Facilities exist now which will enable astronomers to conduct surveys that both cover moderately large areas and extend to quite large distances (and, hence, probe farther back into time). Three-dimensional surveys of a million or more nearby galaxies, and of thousands of galaxy clusters, are underway. The study of large-scale structure at high redshift is also now becoming accessible. It is likely the next decade will see many breakthroughs in this particular area thanks to an array of large optical and near-infrared optimized telescopes being commissioned over the next several years.

The COBE satellite provided constraints on the distribution of fluctuations in the matter distribution in the very young universe but only on extremely large scales (greater than 600 Mpc). CMB observatories in space to be launched early in the 21st century will yield exquisite constraints on the early matter distribution on scales comparable with those probed by existing redshift surveys and, thus, provide a direct point of comparison for evolutionary studies. Like the peculiar velocity surveys, the CMB studies are attractive because the fluctuations in the microwave background are direct, unbiased tracers of the underlying matter distribution.

But our ability to observe the universe must be matched with an equal ability to interpret and understand the observations. Thanks to revolutions in computer processing power and data storage capacity, experiments to simulate large segments of the cosmos are now underway (see UNIVERSE: SIMULATIONS OF STRUCTURE AND GALAXY FORMATION). These simulations track the trajectories of a billion particles as they evolve over cosmic time to form structure. Such new tools will provide theoretical predictions at a level of detail and accuracy hitherto unavailable. And since the differences between some cosmological models are quite subtle, such a capability is indispensable.

Diurnal Motion

The apparent daily motion of a celestial body across the sky from east to west caused by the axial rotation of the Earth. Diurnal motion causes stars to appear to trace out circles centered on the celestial poles. For an observer at the north or south pole of the Earth, the diurnal motion of stars is along circles parallel to the horizon, while, viewed from the equator, stars trace out paths that intersect the horizon at right angles. In general, the arcs along which stars appear to move intersect the horizon at an angle equal to 90° minus the observer's latitude.

Divided Instruments

Although the division of the zodiac into 360° probably derives from Egypt or Assyria around 2000 BC, there is no surviving evidence of Mesopotamian cultures embodying this division into a mathematical instrument. Almost certainly, however, it was from Babylonia that the Greek geometers learned of the 360° circle, and by c. 80 BC they had incorporated it into that remarkably elaborate device generally called the 'Antikythera mechanism'. This mechanism, found in 1900 by sponge divers in the remains of a ship which sank around 180 BC off the Greek island of Antikythera, is a sophisticated geared instrument that could be used to compute the motions of the planets. It is ironic, therefore, that the earliest known graduated astronomical instrument should already be one of great complexity, pointing to both a highly developed astronomical geometry and a complementarily mature state of instrumental craftsmanship in classical Greece.

Ptolemy's influence

In his encyclopaedic *Mathematical Composition*, or *Almagest*, of c. AD 150, Claudius PTOLEMY describes the uses of a variety of astronomical instruments capable of measuring the positions of the heavenly bodies from fixed coordinates by means of the 360° scale. These include the astrolabon and quadrant, as well as adaptations of the linear properties of the circle whereby angles could be measured using straight rods arranged in triangular configurations by means of sines and tangents.

Ptolemy's astrolabon is really a set of armillary rings, in brass or bronze, aligned with the main planes of the sky, such as the zodiac, celestial equator and meridian. Graduated into 360°, these rings could be used to track the motions of astronomical bodies across the sky, so that tables of observations could be compiled, from which theories could be generated. The two-dimensional 'astrolabe' was constructed by an ingenious flattening of these rings onto a series of plates to produce a stereographic projection of the sky in the form of a planisphere. It was the Arab astronomers of the 7th century AD who developed the astrolabe in the form in which it became familiar in the Latin West in the 12th century, turning it into a dual-function instrument that could be used both to observe the altitudes of bodies and to perform practical calculations in spherical trigonometry.

The division of angles into ever-decreasing units of minutes and seconds, where the accuracy of each digit of division could be relied on geometrically and scientifically, became a concern to those cultures that placed a high premium on astronomical research. In the post-classical world, this meant the Arabs, who developed two classes of graduated astronomical instruments. The first of these were large instruments, often built in masonry, in which accuracy was achieved by the greatness of the radius employed. The 1424 observatory of ULUGH BEG of Samarkand with its 130 ft radius meridian sextant set in a drum-shaped building housed the most spectacular and successful instrument of this type, which was capable, in theory, of measuring the solar declination and stellar, lunar and planetary altitudes to within a few arcseconds.

The second class of graduated instruments to come out of the medieval Islamic world were what might be called reckoning instruments. These included the astrolabe, hand quadrant and forms of cross-staves. They were not sufficiently accurate to re-define any astronomical constants, but were intended, with their scales divided to 1° or perhaps 30 arcmin, to measure solar or other data for the daily business of time-finding, navigation, surveying, religious liturgy or astrology. This class of instruments generated the world's first trade in divided scientific artefacts of which a large number of individual examples, especially astrolabes, survive in museum collections around the world.

The astrolabe

The astrolabe came into Europe via Muslim contacts (see ASTROLABE). The astrolabe was not an instrument of original research but a reckoning instrument, whereby one could establish local time by Sun and stars, as well as compute a wide range of calendrical features. Each instrument carried two 360° scales, on the back and front of the main brass plate. The rear scale was used to make celestial observations by means of a sighting alidade, while the front, in conjunction with the stereographically projected sky of 'climate' plates, could be used to calculate the aforementioned horological and calendrical data.

Studies in a range of surviving European astrolabes, made between c 1380 and 1650, indicate that several geometrical configurations, employing scribing compasses and copy-templates, were used in various workshops to generate the 360° scales, and by 1500 there seem to have been established centers, such as Florence and Augsburg, for the manufacture of astrolabes, dials and similar mathematical instruments.

Tycho Brahe

It was the Danish nobleman TYCHO BRAHE, between 1572 and 1598, who became the first European to devise relatively large-radius graduated instruments intended for original research. These included a collection of ARMILLARY SPHERES (set in zodiac and equatorial coordinates), quadrants, sextants, rulers of parallax (or triqueta), globes and clocks with which he performed the first fundamental revision of the positions of the heavenly bodies since Ptolemy 1300 yr before.

Unlike Ulugh Beg and other Muslim astronomers with whose observations he was familiar, Tycho abandoned the idea of building very large radius instruments after a 14 cubit (19 ft) radius quadrant which he had built with Paul Hainzel of Augsburg showed signs of distorting under its own weight. Tycho went on to become the first person to analyze graduated instruments as engineering structures, realizing that stability of the entire instrument was essential if the scale graduations were to remain true. Instead of making instruments of tens of feet radius,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

as a way of making the graduations bigger, he adopted and greatly improved the transversal or diagonal scale: a device going back to Richard Cantzlar and LEVI BEN GERSON. In the diagonal scale, the degree space is seen not simply as a line, but as a two-dimensional area extending across part of the radius. A line, drawn diagonally across the area, and divided into 30 or 60 equal spaces, could then allow a degree to be read to a small fraction from an overall radius of only 6 ft or so. All of Tycho's mature instruments carried diagonals, as did those of most of his successors—Pierre GASSENDI, Giovanni CASSINI, Johannes HEVELIUS and John FLAMSTEED—over the next 130 yr. Tycho Brahe was proud to inherit the triquetum, or set of so-called 'Ptolemy's Rulers', of NICOLAUS COPERNICUS presented to him by Johannes Hannow, Canon of Ermeland. The Rulers consisted of three straight rods and read an angle by using the geometrical relationship of the tangent to the radius and circumference of a circle. The instrument's advantage lay in the relative ease whereby one could divide a straight line into equal parts as opposed to a 90° arc, although, as Tycho found after exhaustive testing, the instrument was not suitable for critically accurate observations.

The ultimate quality of Tycho's positional observations—averaging 1 arcmin, as opposed to 10–15 arcmin for his predecessors—derived from his constant analysis, re-designing and increasing specialization of function of his observatory instruments. Tycho's concern with error detection and correction when it came to both the geometrical and the engineering construction of his instruments constituted a landmark in instrument technology and convinced scientists that their observations, and the plausible theories that they could build on them, were only as good as the graduated scales at their disposal.

Renaissance Europe saw an explosion of ingenuity in the devising of angle-measuring instruments, aimed at the specialist needs not just of astronomers, but also of navigators, surveyors, gunners and mathematical teachers. The principles implicit in Ptolemy's Rulers, whereby straight rods were adapted to read angles, were made use of to produce the mariner's cross-staff, the baculus and their variants. Indeed, even some astronomers of distinction did important angle-measuring work with straight instruments, the most outstanding of whom were Thomas HARRIOT, Pierre Gassendi and Jeremiah HORROCKS.

Intellectual pressures

The intellectual pressures generated by the Copernican revolution, initially exemplified in the path beaten by Tycho Brahe, encouraged European astronomers to search for and quantify a stellar parallax by which the Earth's motion could be physically demonstrated. Also, after 1670, and especially after NEWTON'S *Principia* in 1687, critical measurements were seen as lying at the heart of the quantification of the solar system and the physical testing of gravitation theory. By 1680, therefore, the improvement of graduated instruments had become an ongoing concern, especially in England, where craftsmen such as Thomas TOMPION, George GRAHAM and Jesse RAMSDEN not only made considerable financial profits from pioneering innovation but also won Fellowships of the Royal Society and international academic recognition as well.

The quadrant, which was the basic angle-measuring instrument of the period 1575–1790, had its divisions struck off on its limb using the canons of Euclidean geometry. The radius of any circle will naturally strike off six 60° arcs into the circumference of the same circle, or go $1\frac{1}{2}$ times into a quadrant. A bisected radius—physically exemplified by the beam compass—then strikes off 30°, so that 60° + 30° produce a perfect quadrantal arc. Further bisections will divide the quadrant down to 15° spaces, after which a variety of geometrically 'impure' trisections and quinquesections will take one down to single degrees, and then to minutes.

The micrometer, telescopic sight and clock

Following Tycho Brahe's lead in the construction of more compact instruments with geometrically complex scales, 17th- and 18th-century instrument makers invented a number of systems whereby diagonals of various forms, combined with vernier scales and micrometers, enabled an instrument of 6 or 7 ft radius to perform much more accurately than a simple masonry quadrant of 100 ft. Indeed, the period 1640–1670 saw an extraordinary increase in the sophistication and accuracy of graduated instruments used in astronomical observatories. The large private observatory of Johannes Hevelius, the instruments of which were described and illustrated in minute detail in his *Machina coelestis* (1673), both built on the Tychonic tradition and at the same time influenced Giovanni Cassini in Paris and John Flamsteed in Greenwich. Also, around 1640, the Yorkshireman William GASCOIGNE invented the micrometer and developed the first workable telescopic sight. Between them these two inventions enabled an over 40-fold increase in the practical sighting of astronomical instruments beyond what was possible with the naked eye. By exploiting the ancient properties of the tangent to the circle, and now made vastly more delicate as a result of precision screw-threads and optical reading, the micrometer made it possible to measure down to a single arcsecond. Neither the telescopic sight nor the micrometer became common, however, until brought to the attention of the wider world of learning by Robert HOOKE in 1667, and they had been only partly used by Hevelius. Also, when the oscillating pendulum was successfully harnessed to the going train of a clock by Christiaan HUYGENS in 1658, and was improved by Hooke's and Joseph Clement's development of the 'seconds pendulum' and anchor escapement around 1669, the new precision clock suddenly became a major angle-measuring instrument in its own right, whereby, in conjunction with a meridian quadrant, it could be used to divide up the sky into hours, minutes and seconds of right ascension.

The ROYAL OBSERVATORY, GREENWICH, under John Flamsteed, the first Astronomer Royal, became the first place

in Europe where these new optical, micrometric and horological techniques of celestial angle measuring were used systematically and with spectacular success, between 1675 and 1719, although valuable work was also done by Cassini and Jean PICARD in Paris, and by Ole Christensen RØMER in Copenhagen.

Cross-checking

During the 18th century, graduated instrument design and use were dominated not only by an ever-increasing pressure towards greater accuracy but also by the evolution of cross-checking and error-detecting techniques whereby both craftsman and astronomer could quantify the errors of their instruments.

Fundamental in this line of development was the 8 ft radius quadrant which George Graham FRS built for Edmond HALLEY at Greenwich in 1725. In addition to its 90° scale, Graham equipped this instrument with a second scale of 96 equal parts, the whole of which could be drawn by 'pure' geometrical bisection: i.e. radius = 64 parts then bisected to 32:16:8:4:2:1, by beam compasses.

These two scales, drawn 1 in apart from the same center, acted as cross-checks on each other, when read against their corresponding micrometers, to reach a new threshold of accuracy. Then, in 1750, John Bird completed a new quadrant for James BRADLEY, Halley's Greenwich successor. Bird's 8 ft quadrant carried a similar specification to Graham's, although its 90° scale incorporated no trisections, for all of its degrees and minutes were struck off from a perfectly straight 'scale of equal parts' by means of beam compasses. Bird's quadrant's 1 arcsec accuracy was also achieved by an all-brass construction, which avoided bimetallic tensions, and by the fitting of superior micrometers. It was this quadrant that enabled Bradley to perform the most accurate angular measurements made to date, while a comparable 6 ft Bird quadrant made it possible for Tobias MAYER of Göttingen to compile the first set of lunar tables that were sufficiently accurate for the longitude at sea to be found.

The circle

By the 1770s, however, inventors such as Jesse Ramsden and John and Edward TROUGHTON, perhaps inspired by the published researches of Michel Ferdinand d'Albert d'Ailly, duc de Chaulnes, had come to realize that full-circular instruments were the only way forward when it came to achieving ever more critical accuracies, for an astronomical circle was capable of being checked and re-checked by means of reticule microscopes set at 180°, 90°, 60° and 30° across its radius in a way that a quadrant was not. Ramsden's 36 in theodolite for the early Ordnance Survey, 1787, and his 5 ft circle for Guiseppe PIAZZI in Palermo, Sicily, in 1789, were the first circular instruments to demonstrate the spectacular accuracy breakthrough permitted by the full-circle design. Subsequent circles made by Edward Troughton for John POND, Stephen Groombridge and others up to 1806 all demonstrated that the 1 arcsec ceiling of the quadrant could be surpassed to 0.1 arcsec with the circle.

All of these circles had to be meticulously hand-graduated, although in 1766 Jesse Ramsden had begun experiments whereby a 36 in diameter, finely denticulated wheel, acted on by a precision worm-wheel, could 'mass produce' nautical instruments, such as sextants, that had become so necessary in finding the longitude by lunars. By the 1840s, however, the vastly increased machine-tool skills of the industrial revolution enabled William Simms to engine-divide the 6 ft transit circle which the Astronomer Royal George Biddell AIRY had designed, and commissioned into the Royal Observatory, in 1850. When fully adjusted, the Airy Transit Circle, by Ransome & Simms, could measure meridian angles to 0.01 arcsec and was to remain in constant daily use until 1954.

Between 1680 and 1850, it was British craftsmen who made most of the major innovations in graduated instruments, although by 1850 the firms of George Friedrich von Reichenbach and Traugott Lebrecht Ertel were producing superlative instruments for an increasingly international market. It was the advent of photography that fundamentally altered the traditional uses of graduated instruments. Also, especially after the establishment of the *Carte du Ciel*, 1887, measurements taken from a photographic plate, rather than through a telescope eyepiece, showed the way forward when it came to measuring star positions.

The European Space Agency's 'HIPPARCOS' stellar photographic project now represents the state of the art in contemporary angle measuring, while even the Royal Greenwich Observatory's last great circle, the Carlsberg Meridian Circle on La Palma in the Canary Islands, measures and records the meridian passage of stars under computer control.

Dixon, Jeremiah (1733–79)

Surveyor and astronomer, born in Bishop Auckland, Durham, England. In 1760 the Royal Society chose CHARLES MASON for an expedition to observe the transit of Venus, and Mason chose Dixon as his assistant, successfully observing the transit at the Cape of Good Hope on 6 June 1761. In 1763 Mason and Dixon traveled to Pennsylvania and Maryland, to define the disputed boundary between the two states; this established the *Mason–Dixon* line, which became synonymous with the boundary between both the political and geographic north and south of America. In 1769 Dixon observed the second transit of Venus of the eighteenth century.

Dobson Unit

The Dobson unit is a measure of atmospheric ozone content. The total amount of ozone in a column of air is expressed as the thickness of the layer of ozone formed on compressing the column to standard temperature and pressure conditions (1 atmosphere and 0 °C). A layer thickness of 0.01 mm corresponds to 1 Dobson unit (DU). 300 DU is a typical global average.

Dobsonian Telescope

A simple, cheap and portable form of Newtonian reflecting telescope mounted on an altazimuth mounting. Attached to a simple fork mounting that rotates in altitude (elevation) and azimuth (parallel to the horizon), with Teflon strips as the bearing surfaces, a Dobsonian telescope, provided it is well balanced, can be moved quickly and smoothly by hand to point towards any part of the sky. Because of its simple mode of construction, aperture for aperture, the Dobsonian is significantly cheaper to construct than other designs. Consequently this design enables amateur astronomers to acquire instruments of relatively large aperture and light-gathering power at relatively low cost.

Dollond, John (1706–61)

Instrument-maker, born in London, Dollond was the first manufacturer to produce achromatic lenses commercially, starting in 1758. The achromat consisted of two lenses in different types of glass. The idea had been put forward by a London barrister, Chester Moor Hall (1703–71), but Dollond carried out the experimental work to realize the achromatic lens. One lens was made of relatively common crown glass, but the other glass, flint, was produced in small quantities. English glassmakers supplied English manufacturers with the best quality and sold rejects elsewhere. Dollond had first choice, and with the protection of his patent exploited his position. But British astronomers had access to excellent instruments and produced excellent science! When the patent expired, the price of achromatic telescopes halved. John Dollond's work was continued by his sons, Peter and John, and by the latter's nephew George Huggins (who, such was the Dollond family's prestige, took the name George Dollond).

Dome

A circular, very shallow-sided hill on the surface of a planetary body. Lunar domes are found in the maria, and are typically 10–15 km across, with gradients of no more than a few degrees. They are volcanic in origin, and some have a small pit at their center; they may mark the tops of the volcanic vents through which the lava that formed the maria emerged.

Dominion Radio Astrophysical Observatory

The Dominion Radio Astrophysical Observatory began operating in 1959, and joined the NATIONAL RESEARCH COUNCIL in 1970. It became part of the Herzberg Institute of Astrophysics in 1975. The site near Penticton, BC has a 26 m radio telescope, a seven-antenna synthesis telescope on a 600 m baseline and two telescopes dedicated to monitoring the solar radio flux at 10.7 cm. This part of the Institute also supports the development of correlators and the design of future radio telescopes.

Doppler Effect

The change in the observed frequency and wavelength of a source of radiation resulting from its motion towards, or away from, the observer. If a source is approaching, the frequency of the radiation is increased (more wavecrests per second reach the observer than would be the case if the source were stationary relative to that observer) and its observed wavelength decreased. If the source is receding, the frequency is decreased and the wavelength of the radiation is increased.

The principle was suggested in 1842 by the German mathematician, Christian Doppler (1803–53). In 1848, the French physicist Hippolyte Fizeau (1819–96) showed that the wavelengths of spectral lines would be affected in the same way. Consequently, lines in the spectrum of a receding source would be displaced towards the longwave (red) end of the spectrum and those in the spectrum of an approaching source would be displaced towards the shortwave (blue) end. The term 'redshift' is applied to the former case and 'blue shift' to the latter.

The observed wavelength, λ', differs from the rest-wavelength (the wavelength measured in a frame of reference in which the source is stationary), λ, by an amount $\Delta\lambda$, which depends upon the radial velocity (speed directly towards or away from the observer) of the source. For velocities, v, which are small compared with the speed of light, c, the wavelength shift is given by:

$$\frac{\Delta\lambda}{\lambda} = \frac{\lambda' - \lambda}{\lambda} = \frac{v}{c}.$$

If the velocity of the source relative to the observer is an appreciable fraction of the speed of light, the relativistic expression:

$$\frac{\Delta\lambda}{\lambda} = \left(\frac{c+v}{c-v}\right)^{1/2} - 1$$

must be used.

The radial velocity of a light source may be determined by comparing the observed wavelengths of its spectral lines with the wavelengths that those lines would have if the source were stationary. The Doppler effect, therefore, provides the means by which the radial and rotational velocities of stars and galaxies may be determined.

Doppler, Johann Christian Andreas (1803–53)

Born in Salzburg, Austria, Doppler studied and taught mathematics in Vienna. On the verge, because of economic hardship, of emigrating to America, he was offered posts in Prague. Despite huge teaching loads, he was able to carry out some research of his own (in the face of complaints of neglect by his students). In 1842 read a paper to the Royal Bohemian Society 'On the colored light of the double stars and certain other stars of the heavens', articulating the *Doppler principle* which relates the frequency (or wavelength) of a source to its velocity relative to an observer. Doppler showed that there would be a change of frequency of both light and sound waves if the source were moving; the change of frequency (or wavelength) is called the *Doppler shift*. He tried to illustrate his theory with an application to the colors of double stars, but the effect is actually too small to produce a major shift of color. He foresaw that his effect 'will in the not too distant future offer astronomers a welcome means to determine the movements and distances of distant stars'.

Dorado

(the Goldfish, or Swordfish—sometimes shown as Xiphias; abbrev. Dor, gen. Doradus; area 179 sq. deg.) A southern constellation which lies between Pictor and Reticulum, and culminates at midnight in early December. It was first shown on Petrus Plancius' celestial globe of *c*. 1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, inconspicuous constellation, the brightest stars in Dorado are α Doradus, magnitude 3.3, and β Doradus, one of the brightest Cepheid variables (range 3.5–4.1, period 9.84 days). There are no other stars brighter than fourth magnitude. The constellation contains most of the Large Magellanic Cloud (LMC, which extends into the neighboring constellation of Mensa), in which interesting objects include S Doradus, an extremely luminous eruptive variable (range 8.6–11.5), and NGC 2070 (the Tatantula Nebula), a large (40′) emission nebula centered on the star 30 Doradus. The part of the LMC in Dorado was also the location of Supernova 1987A.

Double Star

The description 'double star' is given to any pair of stars that appear close together in the sky. Double stars fall into two distinct classes: those pairs that are actually close together in space and are therefore physically linked, and those that may be very far apart in space but happen to lie in almost the same direction.

A pair of stars that really is close together has a common gravitational field and is termed a 'binary system'. The term 'physical double' is also sometimes used. Although there are often two principal components, many systems have additional members and so constitute a 'multiple star' system. Stars that appear to be double only because they happen to lie in almost the same line of sight are termed 'optical doubles'. There is no way of distinguishing between the two classes from a single observation, but while the relative position of the components of an optical double remains fixed, or changes by the straight-line relative proper motion vector, members of a binary system are in orbit around a common center of gravity and their accelerating orbital movements can be revealed by an extended series of observations. The orbital periods are usually very long, measured in decades or even centuries, so that these observations must be made over a correspondingly long period of time.

Statistical analysis shows that a large majority of the closer double stars are physical binary systems rather than optical pairs, but many double stars are difficult to identify with certainty as close binary or multiple systems, unless they are included in a major program of observation which will require the use of a powerful telescope for extended periods every few years throughout much of its working life. Such lengthy programs can rarely be allowed to take precedence over work that offers more immediate results, unless the suspected double stars in question are of particular interest, for example as members of an important moving cluster of stars.

Double Stars: Visual and Imaging Observations by Amateurs

Measurements of the position angle and separation with time of visual double stars allow the apparent orbit of the two stars to be calculated and hence the total mass of the two stars derived (figures 1 and 2). It is still one of the best ways of calculating stellar masses but the long period of many visual binary systems (typically a few hundred years) means that the number of reliable orbits is still very small (currently about 50).

Amateur observers have a long and distinguished record in the annals of double star observing. S W Burnham started out with a small refractor and later made it his life's work, holding down a day job as a clerk in a Chicago court and at weekends observing at Yerkes Observatory. He later became a professional. In England, T H E C Espin discovered several thousand faint and wide pairs with his reflectors and significant contributions were also made by W R Dawes (both, incidentally, clergymen). The greatest amateur was the Frenchman Paul Baize, by day a pediatrician, who made 24 000 measurements and computed nearly 500 orbits and is tenth on the all-time list of observers.

The filar micrometer (figure 3), invented in the 1640s and still in use today, is one of the chosen instruments for those who want to push their telescopes to the limit of resolution. The human eye is still the best detector for pairs which are close or unequal, and a good 35 cm telescope will allow pairs as close as 0.25 arcsec to be measured. Another effective instrument is the double-image (or Lyot) micrometer which is perhaps better than the filar for small separations but cannot match the range of separations that the filar can handle.

While many bright pairs have orbits which require little further adjustment there are a large number of fainter pairs which require attention. In addition the

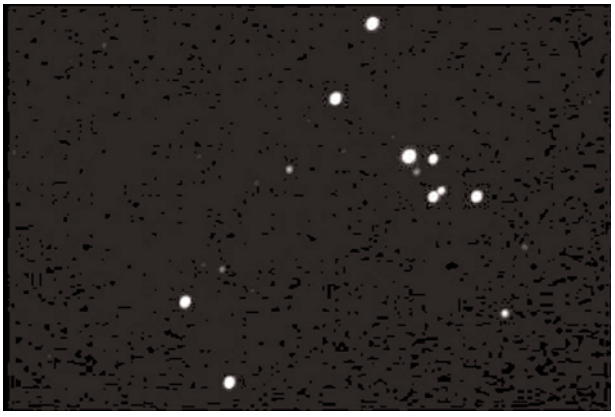

Figure 1. The multiple star HJ 684 located in the cluster NGC 1662 in Orion, imaged by Martin Nicholson. The bright close pair center right is CD—magnitudes 10.3 and 12.5, PA is 308.72°, and separation 10.26 arcsec. These components were previously measured in 1910 and 1987 only. The field size is 10 arcmin × 6 arcmin. North is to the top and east to the left. This is one of six 2 s exposures. Credit: Martin Nicholson, Daventry Observatory.

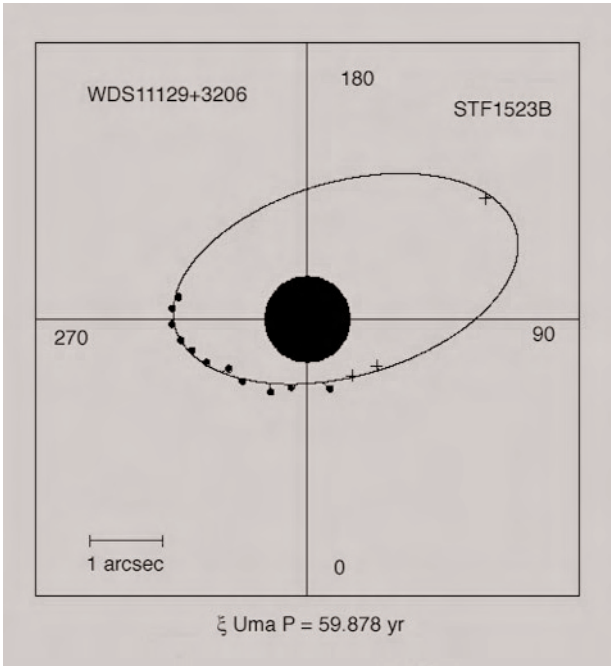

Figure 2. The pair ξ UMa—observed by R W Argyle between 1970 and 2002. The full curve shows the current orbit for this pair. The full dots represent means of five or more nights, the crosses one to five nights. The solitary single cross is an observation made in 1970 and the motion is clockwise. The radius of the central circle is the angular resolution of the telescope—in this case 0".56.

Figure 3. The RETEL filar micrometer used by the writer. It uses parallel wires (one movable and one fixed) to measure separation and a third wire at right angles to measure position angle. The whole field is illuminated by means of a variable-intensity red light-emitting diode. Credit: Richard Sword, Institute of Astronomy, Cambridge.

Dirac House, Temple Back, Bristol, BS21 6BE, UK

Hipparcos satellite has discovered thousands of new pairs most of which have not yet been followed from the ground and all of which need to be.

While the filar micrometer has been the mainstay of this work for centuries, the advent of charge-coupled device (CCD) cameras means that there is an opportunity for amateurs equipped with small to medium apertures to make substantial contributions (see CCDs, FILTERS AND CCD PHOTOMETRY FOR AMATEURS). In particular there are many thousands of faint pairs on the various Schmidt sky surveys which are completely unrecorded and measured. Using a 12 in Schmidt–Cassegrain and an SBIG CCD for instance, Martin Nicholson, working at Daventry near Northampton, has found many new pairs using the Guide Star Catalogue. Pairs as close as 5 arcsec and as faint as magnitude 15 can be imaged routinely with his 12 in Meade LX200 and SBIG ST7-E CCD. Reduction of the CCD frames is made using the IRAF suite of image-processing routines.

Another advantage of the CCD camera is that, with the appropriate filters, it can be used to determine the colors of each component of resolved double stars. Many pairs in the Washington Double Star catalogue have not been observed photometrically and much remains to be done here.

In the field of double star observing, there is much that modern amateurs can do. They can continue to monitor the longer-period pairs and lay down measures for future orbital determination. The United States Naval Observatory webpage points to all the data needed. The WDS catalogue is as inclusive as its maintainers can make it (it currently contains over 99 000 entries) and the Sixth Orbital catalogue lists all the orbits deemed worthy of printing. The quality of each orbit has been determined—grade 1 is definitive and grade 5 is indeterminate. Any pairs with orbits of grade 2 or lower could usefully be observed.

Amateurs with a large enough aperture (30 cm or more) could examine and measure the new double stars in the Hipparcos or Tycho catalogues. All are listed in the WDS catalogue which is available both on-line and as a CD-ROM which can be requested free of charge from USNO.

In addition, the power of the modern Schmidt surveys can be utilized to measure and catalogue many faint pairs which have been ignored up until now. Finally, a CCD could be used to great effect on a photometric program of double stars. Many pairs have the magnitudes assigned to them by their discoverers—usually eye estimates. Little is known about the colors of these stars or how many are variable. With a double star there is a built-in comparison for photometry.

Those intending to make a serious contribution must consider how to publish their measurements. These can be submitted to professional journals such as *Astronomy and Astrophysics* while specialist amateur groups such as the Webb Society, the Iberoamerican League for Astronomy (LIADA) and the Société Astronomique de France also offer this service.

DQ Herculis

The old NOVA DQ Herculis (Nova Herculis 1934) is the prototype of its CATACLYSMIC BINARY sub-class, distinguished by a rapidly rotating weak-field magnetic WHITE DWARF accreting primary. The magnetic moments in the DQ Her white dwarfs are weak enough (10^{32}–10^{34} G cm^3) that the Keplerian-disk ACCRETION flow is broken up only a few stellar radii above the white dwarf surface. The infall is still energetic enough that accretion columns (or curtains) emit significant soft x-ray/UV radiation. These rotating radiation sources illuminate and photoionize the disk surface as a sweeping beam. The subsequent electron–ion recombination yields a sweeping wave of Balmer emission from the disk surface, and this 'reprocessed' radiation can in certain geometries be observed as a periodic photometric signal.

Table 1. DQ Her system parameters.

Orbital period	P (hr)	4.56
Mass ratio M_2/M_1	q	0.66
Primary mass	$M_1/M_\odot$	0.60 ± 0.07
Secondary mass	$M_2/M_\odot$	0.40 ± 0.05
Orbital separation	$a/R_\odot$	1.41 ± 0.05

DQ Her itself is an ECLIPSING BINARY system with $P_{\rm orb} = 4^{\rm h}39^{\rm m}$. Other observationally determined system parameters are given in table 1. In the late 1950s the system held for many years the record for the shortest photometric period in an astronomical source—the 71-s white dwarf spin period—which has an observed amplitude of roughly 1%. What remains remarkable today is the system's high inclination of $i \approx 89.5^\circ$. The white dwarf primary is eclipsed by the edge-on ACCRETION DISK, and only a thin sliver of the back face of the the accretion disk contributes to the pulsed radiation received from DQ Her. Variations in the phase of the 71-s signal during eclipse ingress and egress—first detected in 1972—led to the rotating magnetic accretor model for DQ Her and related systems. Significant variations in phase observed *outside* eclipse result from the self-eclipse of a non-axisymmetric disk, and provide a means to probe the time-averaged structure of an accretion disk at high state, i.e. a disk that has a high mass-transfer rate and high viscosity.

Eclipse-related phase variations

Figure 1 shows schematically but approximately to scale a $q = 0.67$ system viewed from an inclination angle of $i = 80^\circ$, and helps convey the origin of the eclipse-related phase shifts. In the figure, the mean opening angle and radius of the reprocessing region are indicated (see also figure 2), and the black wedge represents the soft x-ray beam sweeping in a prograde direction. If we assume for now that the disk has a constant radius and opening angle for all azimuthal angles, then out of eclipse the times of pulse maxima occur when the beam is centered on the back face of the disk. As the disk reprocessing region is covered during eclipse ingress, the pulses appear to arrive progressively earlier as the latter portion of the pulses are eclipsed by the secondary, arriving one-quarter cycle early just before the total eclipse of the reprocessing region. During egress, the situation is reversed: the first pulse arrives one-quarter cycle late relative to the out-of-eclipse ephemeris, and pulses arrive progressively earlier as the reprocessing region is uncovered.

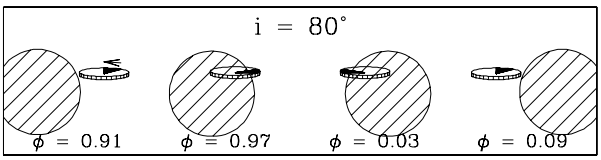

Figure 1. A line drawing (approximately to scale) of DQ Her passing through eclipse, as viewed from an inclination angle of $i = 80^\circ$. The EUV/x-ray beam is represented as a wedge on the disk surface, with the direction of rotation indicated with the arrow. The accreting white dwarf is located at the apex of the wedge. During ingress (egress) the reprocessed pulses will arrive earlier (later) than when out of eclipse. Note that the non-zero disk opening angle results in a front/back asymmetry in the visibility of the disk surface. For inclinations $i \geq 86^\circ$ only a thin strip at the top of the back rim is visible—the white dwarf is eclipsed by the disk.

If as in figure 1 the opening angle of the reprocessing region was constant, then the time center of the pulse would always correspond to the beam passing the back center of the disk, and the only out-of-eclipse phase variations would be those arising from the light travel time delay across the orbit. However, DQ Her exhibits significantly larger variations in the phase of the 71-s signal, and these must result from variations in the rim height of the reprocessing region.

The time-averaged disk structure

Numerical hydrodynamical simulations (smoothed particle hydrodynamics, SPH) of a three-dimensional disk at equilibrium yield an estimate of the radial extent of the reprocessing region and any dependence of the region's rim height as a function of azimuthal angle. Figure 2 shows a top view (x–y projection) of 20 000 SPH simulation particles, center of mass, the stellar surfaces, the orbit with $P_{\rm orb} = 71$ s, the radial extent of the reprocessing region, and the disk opening angle versus azimuthal angle results. Also shown are the viewing angles at the beginning (end) of eclipse ingress (egress). These are consistent with the size of the reprocessing region determined by finding the disk inflection point beyond which surface elements are eclipsed from the primary by intervening disk material. The reprocessing region is found to be nearly circular, simplifying the analysis to modeling a cylinder of non-uniform height. The heavy solid line in the figure shows the opening angle of the reprocessing region (height of the cylinder) as a function of azimuthal angle.

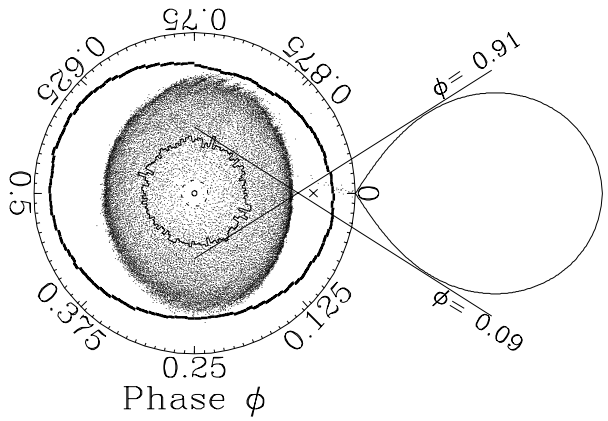

Figure 2. The stellar surfaces and 20 000 SPH (x, y) positions are shown, in addition to the system center of mass '×', the radius with orbital period of 71 s (dotted line), the radius of the reprocessing region, and the opening angle of the reprocessing region (heavy line). The angular scale shows units of phase centered on the primary, and viewing angles of $\phi = 0.91$ and 0.09 are shown.

There are several features of note in this figure. First, most of the mass—evident from the surface density of points—flows in the non-circular outer streamlines in the disk. This is likely to be a general result for a disk in a permanent high state. Second, and also likely to be a general result, the reprocessing region is nearly circular with a radius roughly half the total radius of the disk. The opening angle of the reprocessing region is largest in the quadrants where the disk radius is smallest, and vice versa. This result is a consequence of the requirement that the angular mass flux must be constant for all azimuthal angles in an equilibrium disk. The double-sinusoid shape of the rim of the reprocessing region will affect the observed phase of the pulse produced by the sweeping beam of ionizing radiation.

The O–C diagram

The O–C phase diagram of the observed 71-s signal averaged over several orbits is obtained by fitting a 3-cycle sine curve in a window that shifts by one cycle between fits. Modeling the reprocessing region as a cylinder of variable height with geometry fixed in the co-rotating frame and determined by time-averaging the hydrodynamical results (figure 2), it is possible to calculate the expected O–C phase diagram by integrating over the visible surface of the back cylinder wall.

The observational and numerical results are shown in figure 3—the agreement is remarkable. The best match occurs for the startlingly small range $89.5^\circ \leq i \leq 89.7^\circ$. Note that if the mean opening angle $\langle\theta\rangle$ given by the numerical simulations is unphysically large, then the estimates of the system inclination would need to be even closer to 90°

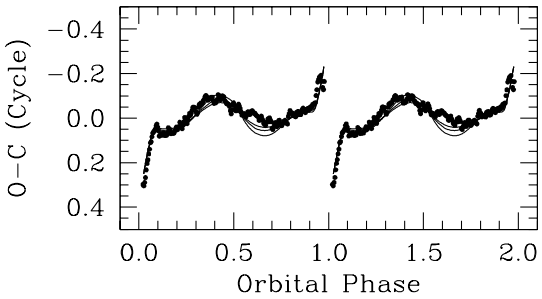

Figure 3. The O–C diagram calculated from the SPH disk structure as a function of orbital phase and for inclination angles ($i = 89.5$, 89.6, and 89.7°. The match is excellent except near orbital phase $\phi = 0.6$.

Spectroscopy

Hubble Space Telescope time-series spectral observations of the Vis/UV continuum and emission lines show that while the UV continuum source is completely eclipsed and the He II emission region nearly so, the N V and Si IV eclipses are deep but not complete, and C IV lines show only a 75% drop. Stellar winds have been suggested as the source of the emission lines, but the behavior is also simply consistent with the geometry in figure 2 if the outer disk is a source of optically-thin emission. The figure shows that while the reprocessing region is completely eclipsed, the outer disk is not.

The general model for DQ Herculis is now reasonably well in hand, but additional observations and simulations are required to understand completely this unique system.

Draco

(the Dragon; abbrev. Dra, gen. Draconis; area 1083 sq. deg.) A northern constellation which lies between Ursa Major and Cepheus, and encloses Ursa Minor on three sides. The center of the constellation culminates at midnight in May, though part of it is on the meridian from mid-February to late July. Draco represents the dragon Ladon in Greek mythology, which guarded the golden apple tree that was given by Mother Earth to the goddess Hera when she married Zeus, and which was killed by Hercules, who is usually shown in early celestial charts with a foot upon Draco's head. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A large but inconspicuous constellation, the brightest stars in Draco are γ Draconis (Eltanin), magnitude 2.2, η Draconis, magnitude 2.7, and β Draconis (Rastaban or Alwaid), magnitude 2.8. There are ten other stars of magnitude 4.0 or brighter, including α Draconis (Thuban or Adib), magnitude 3.7, which was the northern pole star about 4800 years ago. Other interesting stars include the binaries ν Draconis, which has bluish-white/white (A4 and A6) components, both of magnitude 4.9, separation $62''$, one of which has an unseen companion, and μ Draconis, which has pale yellow (F7) components, both of magnitude 5.8, separation $2.2''$, and a third component of magnitude 13. Another interesting object is NGC 6543, a ninth-magnitude planetary nebula, in which, in 1864, William Huggins first observed 'nebular lines' typical of a large mass of hot luminous gas.

The meteor shower known as the Giacobinids (Draconids) appears to radiate from the constellation.

Drake, Frank Donald (1930–)

Born in Chicago, in 1958 he joined the newly founded National Radio Astronomy Observatory (NRAO) in Green Bank, West Virginia, and attempted the first search for extraterrestrial broadcasts, a two week observation of the stars Tau Ceti and Epsilon Eridani. Developed the *Drake equation* as a way to estimate how many intelligent, communicating civilizations there are in our galaxy. The Drake equation multiplies the number of stars in the Milky Way by the fraction which have orbiting planets, then by the number of planets per star that are capable of sustaining life, then by the fraction of these planets where life actually evolves, then by the fraction of these where the life is intelligent and communicates, and then by the fraction of the planet's life during which the communicating civilizations live. This represents an estimate of the number of communicating civilizations in the Galaxy. The real value of the Drake equation is not in the answer itself, but the questions that are prompted when attempting to come up with an answer.

Dreyer, John Louis Emil (1852–1926)

Danish astronomer, born in Copenhagen, who, after working at Birr Castle in Ireland, became director of Armagh Observatory, studying the many nebulae he had previously observed at Birr. At a time when it was not clear whether spiral nebulae were inside our own Galaxy (the Milky Way) or were indeed, as was suspected, island universes outside, he established through careful measurements that they had no proper motion and were likely to be distant. Compiled the *New General Catalogue of Nebulae and Clusters of Stars* (known as NGC) which remains the principal catalog of nebulae and galaxies; it was based on observations by the Herschels (see HERSCHEL FAMILY) and by LORD ROSSE, Dreyer and associates at Birr and Armagh. When government funds for observing were withdrawn from Armagh, as a result of the disestablishment of the Church of Ireland, Dreyer turned to astronomical history, publishing TYCHO BRAHE'S observations and *The History of the Planetary System from Thales to Kepler*.

Dudley Observatory

The Dudley Observatory, in Schenectady, New York, is a private foundation supporting research and education in astronomy, astrophysics and the history of astronomy. Chartered in 1852, it is the oldest organization in the US, outside academia and government, dedicated to the support of astronomical research. For more than a century it was a world leader in astrometry, with such achievements as publication in 1937 of the *General Catalog of 33,342 Stars for the Epoch 1950*.

Dumbbell Nebula (M27, NGC 6853)

A planetary nebula in the constellation Vulpecula, position RA $19^{h}\,59.6^{m}$, dec. $+22^{\circ}\,43'$, and the first to be discovered, by Charles Messier in 1764. It measures $8'$ by $4'$ and is of eighth magnitude. The bipolar expulsion of material from the thirteenth-magnitude central star gives it its twin-lobed appearance; it was named by Thomas Webb, though it resembles a bow-tie more than a dumbbell.

Dunsink Observatory

Designed by Henry Ussher, the first astronomy professor of Trinity College Dublin, Dunsink Observatory (1783) incorporated modern designs such as ventilation in the observation room and a free-standing telescope support column. Among the past directors were the mathematician W R Hamilton (1827–65) and stellar dynamicist H C Plummer (1912–21). The main remaining instrument is a Grubb 12 ft (3.66 m) refractor (1868). Part of the Dublin Institute for Advanced Studies since 1947, the observatory currently concentrates on high-energy studies of extragalactic objects.

Dust Tail, Cometary

The part of a comet consisting of dust grains, carried away from the nucleus by the outflow of gas from the coma during a close approach to the Sun, which are propelled away from the comet's head by radiation pressure. Not all comets develop a dust tail (or a gas tail), but both types of tail always point away from the Sun. The combined effects of radiation pressure and the Sun's gravity acting on the dust particles make dust tails curved, in contrast to gas tails, which are straight. Dust tails shine only by reflected sunlight, so their color is yellow. Their length is typically 10^6–10^7 km, and like gas tails they begin to form at around 2 AU from the Sun. Most of the particles in a dust tail are less than 1 μm across. Larger particles remain in the comet's orbit and form meteor streams.

See: cometary atmosphere, cometary tails, meteor stream, Poynting–Robertson effect.

Compare: gas tail, cometary.

Dusty Circumstellar Disks

What are circumstellar (CS) disks and why should we care about them? Disks appear at many scales in astronomy—from SPIRAL GALAXIES to PLANETARY RINGS. In the present article our concern is with rings or disks that contain particulate material and which orbit stars at various stages in their life cycles. For main sequence stars such as the Sun, the primary interest in such disks is that they could be related to the formation and/or existence of PLANETS and smaller objects like COMETS and ASTEROIDS. After stars have evolved beyond the main sequence orbiting disks are rare and often portend unusual, unexpected, and still unexplained phenomena.

The discovery of dusty CS disks around stars was perhaps the most notable achievement of the INFRARED ASTRONOMY SATELLITE (IRAS) which flew in 1983. IRAS, a joint venture of the United States, the Netherlands and the United Kingdom, found that some bright nearby stars, including VEGA and FOMALHAUT, emit much more radiation at wavelengths between 25 and 100 μm than can be produced solely by the stellar photospheres. The spectral energy distribution of this excess infrared (IR) radiation is generally consistent with models wherein the emission arises from dust particles in circumstellar disks whose characteristic radii are a few tens or hundreds of astronomical units (AU). These grains absorb the optical and ultraviolet light from the central star and then radiate this energy away in the IR. Such stars have been dubbed 'Vega-like'.

At most stars, the particles emit most vigorously at wavelengths between 25 and 200 μm which are difficult or impossible to study from the ground. So, observational progress has been slow in the years since IRAS flew. Indeed, for about 15 years, excepting one star (β PICTORIS), no one was able to image the distribution of dust particles around the Vega-like stars.

Recently, there have been significant observational breakthroughs. From the ground, with very sensitive detectors on large telescopes, images have, at last, been obtained of disks that orbit a few of the Vega-like stars (including Vega itself). These observations have been of thermal emission from the grains at IR wavelengths between 10 and 25 μm and, also, at much longer wavelengths in the radio band near 1 millimeter. In addition, the NICMOS camera on the HUBBLE SPACE TELESCOPE (HST) has imaged 1–2 μm radiation scattered by grains orbiting in disks and rings around a few stars.

Although most of the detected material in most of the disks consists of small particles, at a few stars modest amounts of gas have also been seen. If one is interested in the formation of comets, asteroids and planets, the dust particles that comprise the disks are relevant to all. On the other hand, the principal relevance of the gas is to the formation of giant gassy planets such as Jupiter and Saturn.

The present article is structured along the lines of STELLAR EVOLUTION. We pick up the story about 10 million years after the formation of a star at the last stages of the pre-main sequence evolution. This is the time when massive disks that surround many T TAURI STARS have, by and large, dissipated and only relatively little gas and dust remain. The formation of larger bodies—'PLANETESIMALS' and planets—is either well along or it will not happen at all. We next consider disks around main sequence stars. These are either remnants of the star formation process or else the debris from destruction of larger objects like comets or asteroids. Evidence for the existence of dusty debris from ancient comets is seen in our own planetary system in the vicinity of the orbit of the Earth.

Finally, we consider stars in post-main sequence stages of evolution—the RED GIANT STARS and WHITE DWARFS. Surprisingly, a small percentage of such stars appears to be surrounded by orbiting dusty disks. The origins of most of these disks are mysteries whose eventual understanding will, no doubt, reveal some interesting and important astronomical phenomena.

We conclude with a brief discussion of some properties of circumstellar dust clouds, in particular, how one may estimate their masses from measured fluxes at submillimeter wavelengths.

The evolution of stars and their circumstellar disks

Pre-main sequence evolution

When intermediate-mass stars form they are often surrounded by massive disks of dust and gas that astronomers can detect via strong IR dust emission and radio emission from carbon monoxide molecules (see YOUNG STELLAR OBJECTS). After a few million years the small particles in the disk that are responsible for the IR emission begin to disappear, either because they clump together or because they are lost from the system. The timescale for loss of small particles can be determined by measuring the amount of material as a function of the age of the young stellar objects.

We want to know how long it takes for the dust particles to disappear because this constrains the time it takes to form planetesimals, i.e. bodies that look like present-day comets and asteroids. We want to know how long it takes the gas to dissipate because this will give an upper limit to the time available to form gas giant planets.

Young stars were initially discovered to lie in or near dusty, interstellar molecular clouds. These stars usually have ages less than a few million years, often the ages are less than one million years. These are the T Tauri stars of about a solar mass or somewhat less and the Herbig Ae

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

stars that are a few times more massive than the Sun and which will evolve into A-type main sequence stars like Vega and Fomalhaut. It has not been easy to find somewhat older T Tauri stars, say in the 10–20 million year range, because such stars are hard to identify with infrared and optical techniques. Recently, all-sky surveys of x-ray emission, especially with the German ROSAT satellite, have enabled detection of many stars that appear to be old T Tauri stars. Such stars can be discovered because they emit x-rays strongly compared to older, main-sequence stars.

Not only has the ROSAT satellite enabled detection of some oldish T Tauri stars in regions surrounding various dusty molecular clouds, but it has enabled the clear recognition of the nearest region of recent star formation—the TW Hydrae Association—named in honor of its first known member, the classical T Tauri star, TW Hya. Combination of ROSAT data, measurements of lithium abundances from optical spectra, and distance determinations with the Hipparcos satellite, indicate that the TW Hya Association is about 10 million years old and only about 50 pc from Earth. This is more than two times closer to Earth than any other known region of significant star formation. It is remarkable that this closest T Tauri Association has gone unrecognized for so long. The primary reason is that the massive molecular cloud from which the Association stars formed has dissipated; the only clouds that remain in the vicinity are those that orbit the stars, i.e. CS disks.

Because of their proximity to Earth, disks around TW Hya Association stars can be studied with special clarity. One of the most interesting Association members is an A-type star, HR 4796. Initially, IRAS discovered that about 0.5% of the total energy from HR 4796 is emitted at infrared wavelengths—HR 4796 is the dustiest A-type star in the Bright Star Catalog. (The BSC lists various properties of nearly 10 000 of the brightest stars in the sky, most of which are bright enough to be seen with the naked eye.) By comparison, other relatively dusty A-type stars like Vega and Fomalhaut emit a 100 times smaller percentage of their total energy at IR wavelengths.

Recently, the 10–20 μm thermal emission from dust heated by HR 4796 was imaged at telescopes in Hawaii and Chile. At about the same time, an image of a narrow ring of dust particles that scatter light at a wavelength of 1.1 μm was obtained with the NICMOS camera on the HST (see figure 1, top panel). The stable containment of the ring particles and the abrupt inner and outer truncation of the ring around this relatively young star implies dynamical constraints imposed by one or more related, but as yet unseen, bodies. How such bodies, presumably planets, could have formed so quickly at such large distances from the star presents an interesting challange to those who model planet formation.

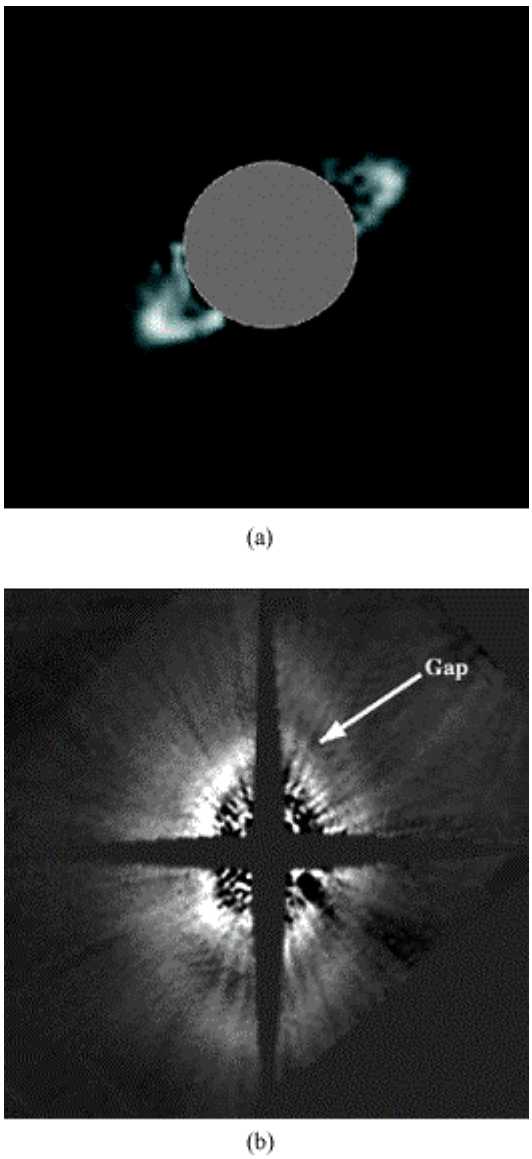

Figure 1. Images obtained at a wavelength of 1.1 μm with the NICMOS infrared camera on the Hubble Space telescope in 1998. The upper panel is HR 4796, a star of age about 10 million years located 67 pc from Earth. The region near the star is unusable and is masked out. The diameter of the surrounding inclined dust ring which reflects 1.1 μm starlight toward the Earth is about 150 AU. The lower panel is HD 141569, a star about 100 pc from Earth whose age is probably less than 10 million years. The diameter of the inclined dusty disk is about 700 AU and there is an indication of a gap between the brightly reflecting dust close to the star and the fainter dust further out. Gaseous carbon monoxide molecules detected in orbit around HD 141569 with a radio telescope seem to be confined primarily to the region interior to the gap. See text for discussion of the structure of the dust at these two stars. (Images courtesy of G Schneider, A Weinberger and P Lowrance.)

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Another A-type star imaged by NICMOS is HD 141569, seen in the lower panel of figure 1. This star is not a member of the TW Hya Association but it was chosen for NICMOS imaging because it has a lot of surrounding dust—about 1% of its energy is emitted at infrared wavelengths—and also surrounding molecular gas. The mass contained in hydrogen molecules orbiting HD 141569 is about 10 Earth masses or more. (No gas has been seen near HR 4796.)

A potentially very exciting aspect of the NICMOS/HST image of HD 141569 is the apparent gap between inner and outer dusty regions. Such a gap would be anticipated if a substantial planet were forming there. HD 141569 is orbited by a companion star, possibly even two companion stars, a few disk diameters away that could also influence the dynamics of the dusty disk.

The brightest molecular emission seen at a star of age about 10 million years is from TW Hya itself (see figure 2). Future observations of these molecules (and others yet to be detected) with sensitive interferometers that operate at millimeter wavelengths promise to help us to better understand the chemical conditions in a potential protoplanetary disk. The interferometers could reveal changes in chemistry as a function of distance from TW Hya. Such chemical data may be helpful to planetary scientists who try to understand the chemistry of our own forming planetary system 10 million years after the formation of the Sun. Chemistry in disks that surround other T Tauri stars can also be studied with future interferometers, but TW Hya should remain unique because it is the closest classical T Tauri star, so finer details can be resolved in its CS disk and, also, because it is the oldest known T Tauri star that still retains substantial quantities of surrounding molecular gas.

The main sequence

Closer to Earth than the TW Hya Association is the best studied of all the Vega-like stars—β Pictoris, a naked eye star located in the southern hemisphere. The age of this A-type star is uncertain; based on its position in a HERTZSPRUNG–RUSSELL diagram, it may be as young as about 10 million years and just arriving on the main sequence, but it could perhaps be as old as 100 million years. This range of plausible ages is narrowed significantly if β Pic formed at about the same time as two low mass (M-type) stars GL 799 and GL 803; because the three stars appear to be moving through space together, they probably did form together. The estimated age of the two M stars is 20±10 million years. Additional evidence in support of this young age is the fact that β Pic is the second dustiest A-type star in the Bright Star Catalog and it seems clear that the amount of dust around stars declines with age (see below). Proper interpretation of the various phenomena seen at β Pic, in the context of the formation of planetary systems, depend on its age.

The disk around β Pic was imaged at a wavelength of 9000 Å with a camera with coronagraphic optics within a year after IRAS discovered the large amount of excess infrared emission. The image revealed that the Earth lies very nearly in the plane of the β Pic disk which extends many hundreds of AU from the star. The initial coronagraphic studies and many subsequent ones in the optical and infrared from the ground and with the HST have revealed many interesting aspects of the β Pic environment. For example, there is a diminution of dust density within a few tens of AU from the star compared to the dust abundance further out along the disk. This might be due to planet formation, but it could also be due to dust destruction or ejection.

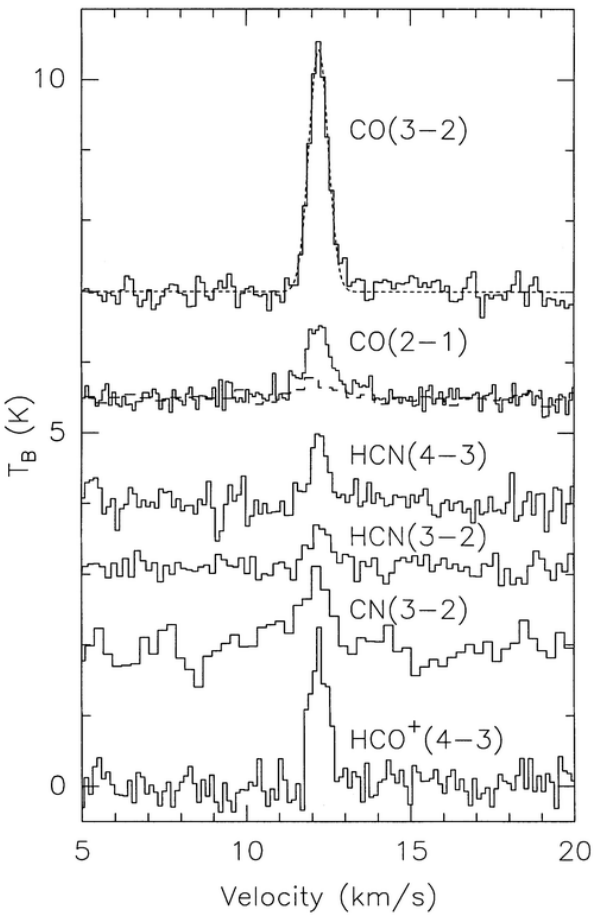

Figure 2. Molecular spectra observed toward TW Hya with the James Clerk Maxwell Telescope at the Mauna Kea Observatory. The abscissa is heliocentric radial velocity and the ordinate is the relative main beam brightness temperature (T_B). The two spectra labeled CO(2-1) are of the ^{12}CO (solid curve) and ^{13}CO (dashed curve) isotopomers (the ^{13}CO spectrum has been expanded along the ordinate by a factor of two). The short dashed curve overlaying the CO(3-2) profile represents the best fit Gaussian function.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Optical spectra of ionized calcium lines show time-variable components. These have been interpreted as due to comet-like objects falling onto β Pic, sometimes as many as a few per week. Modest masses of carbon monoxide (CO) molecules and neutral carbon atoms have been detected in the ultraviolet spectrum of β Pic with HST. It is suggested that these gaseous species result from evaporation of comet-like bodies out to ~100 AU from β Pic. In spite of deep searches, radio astronomers have not yet been able to detect CO near β Pic.

Precise optical images of the disk were interpreted initially as showing a warp, but recent coronagraphic images obtained with the HST suggest that the apparent warp may rather be the superposition of two disk-like components inclined with respect to each other by 4º. Such a structure might be produced by the gravitational influence of a giant planet in orbit around β Pic.

Finally, images obtained at a wavelength of 850 μm show the unexpected presence of an emission peak offset from β Pic by about 34 seconds of arc to the southwest (see figure 3(b)). It is not known if this emission is associated with the star or is, rather, a totally unrelated background galaxy located near the edge of the observable universe! If the emission is associated with β Pic, then it is about 650 AU from the star. It must be due to warm dust grains, since companion stars and planets would radiate too faintly at 850 μm to be detected from Earth. The dust cannot be associated with a companion star, since such a star would easily be seen in the IR. Perhaps there is a brown dwarf or giant planet companion embedded in the dust (see EXTRASOLAR PLANETARY COMPANIONS AND BROWN DWARFS)? But, if so, then unless β Pic is quite young, it is hard to understand how so much dust could be retained for so long near the companion. Perhaps there is an asymmetrical ring that surrounds β Pic well outside of the inner, previously known disk. But, if so, then how did the outer ring get to be so asymmetric with so much dust toward the south-west and so relatively little toward the north-east?

Observations in 2001 by the European Southern Observatory's New Technology Telescope reveal dusty disks surrounding brown dwarfs in the Orion Nebula, suggesting that they are more star-like than planet-like and have the potential to form accompanying planetary systems. This finding is based on detailed observations with SOFI, a specialized infrared-sensitive instrument at the European Southern Observatory's (ESO) 3.5 m New Technology Telescope (NTT) at the La Silla Observatory.

Moving along to older stars, 850 μm images of three are displayed in figure 3. Vega and Fomalhaut are nearby A-type stars, whereas ε Eri (K-type) is even nearer but with mass only slightly less than that of our Sun. These stars were chosen for imaging because they are among the strongest of the excess IR emitters detected by IRAS. The images seen in figure 3 are the first ever of the dust distribution around these three stars. The easiest to interpret is Fomalhaut which is consistent with a ring of material located about 80 AU from the star. As in the case of β Pic, we view Fomalhaut more or less in the plane of its dusty disk. The dust at ε Eri also is distributed in a ring-like manner, but here we view the disk face on; that is, the dust orbits the star at distance of about 60 AU and nearly in the plane of the sky.

An obvious interpretation of the dust rings at ε Eri and at Fomalhaut is that we are seeing analogs of the so-called KUIPER BELT of comets that orbits the Sun just outside of the orbits of Pluto and Neptune. In the case of ε Eri and Fomalhaut, we are not seeing comets directly, but rather millimeter-size dust particles that are produced by the (partial) destruction of comets, probably many more than exist in the Kuiper belt. Given that the ages of ε Eri and Fomalhaut are estimated to be of the order of a few 100 million years, we may speculate that we are seeing structures that are now quite similar to what our own Kuiper belt must have been like billions of years ago.

The regions of relatively low 850 μm emission inside of the dust rings at ε Eri and Fomalhaut might be caused by the formation of planets. In the case of Fomalhaut, another conceivable explanation for the central cavity could be sublimation of icy dust particles during the lifetime of the disk. But such an explanation will not explain the region of relatively low dust abundance near ε Eri because the star is insufficiently luminous to vaporize icy grains.

The image of ε Eri has a surprising feature—a peak of emission in the ring to the east and slightly south of the star. Assuming that this is a real non-uniformity in the ring structure, then it is not easily explained. Perhaps a planet or a 'cosmic collision' can produce structure in the distribution of dust particles.

Finally, Vega presents yet another mystery. As may be seen in figure 3(c), the peak 850 μm emission seems to lie off to one side of the star. As at β Pic, it is conceivable, albeit unlikely, that the emission peak is due to a distant background galaxy. But if the peak in 850 μm emission is due to dust in orbit around Vega, then, as at ε Eri and β Pic, we do not understand the cause of the emission. In particular, since Vega is probably at least 300 million years old it seems most unlikely that dust could be retained in orbit around a substellar companion for so long.

Vega and Fomalhaut with probable ages of hundreds of millions of years are less dusty than HR 4796 and β Pic whose ages are ten to tens of millions of years. More generally, far IR observations of main sequence stars in nearby young clusters and in the field indicate that as stars age, on average, less and less dust is retained in their vicinity. And for stars older than about 20 million years there is little evidence for orbiting gas. Most

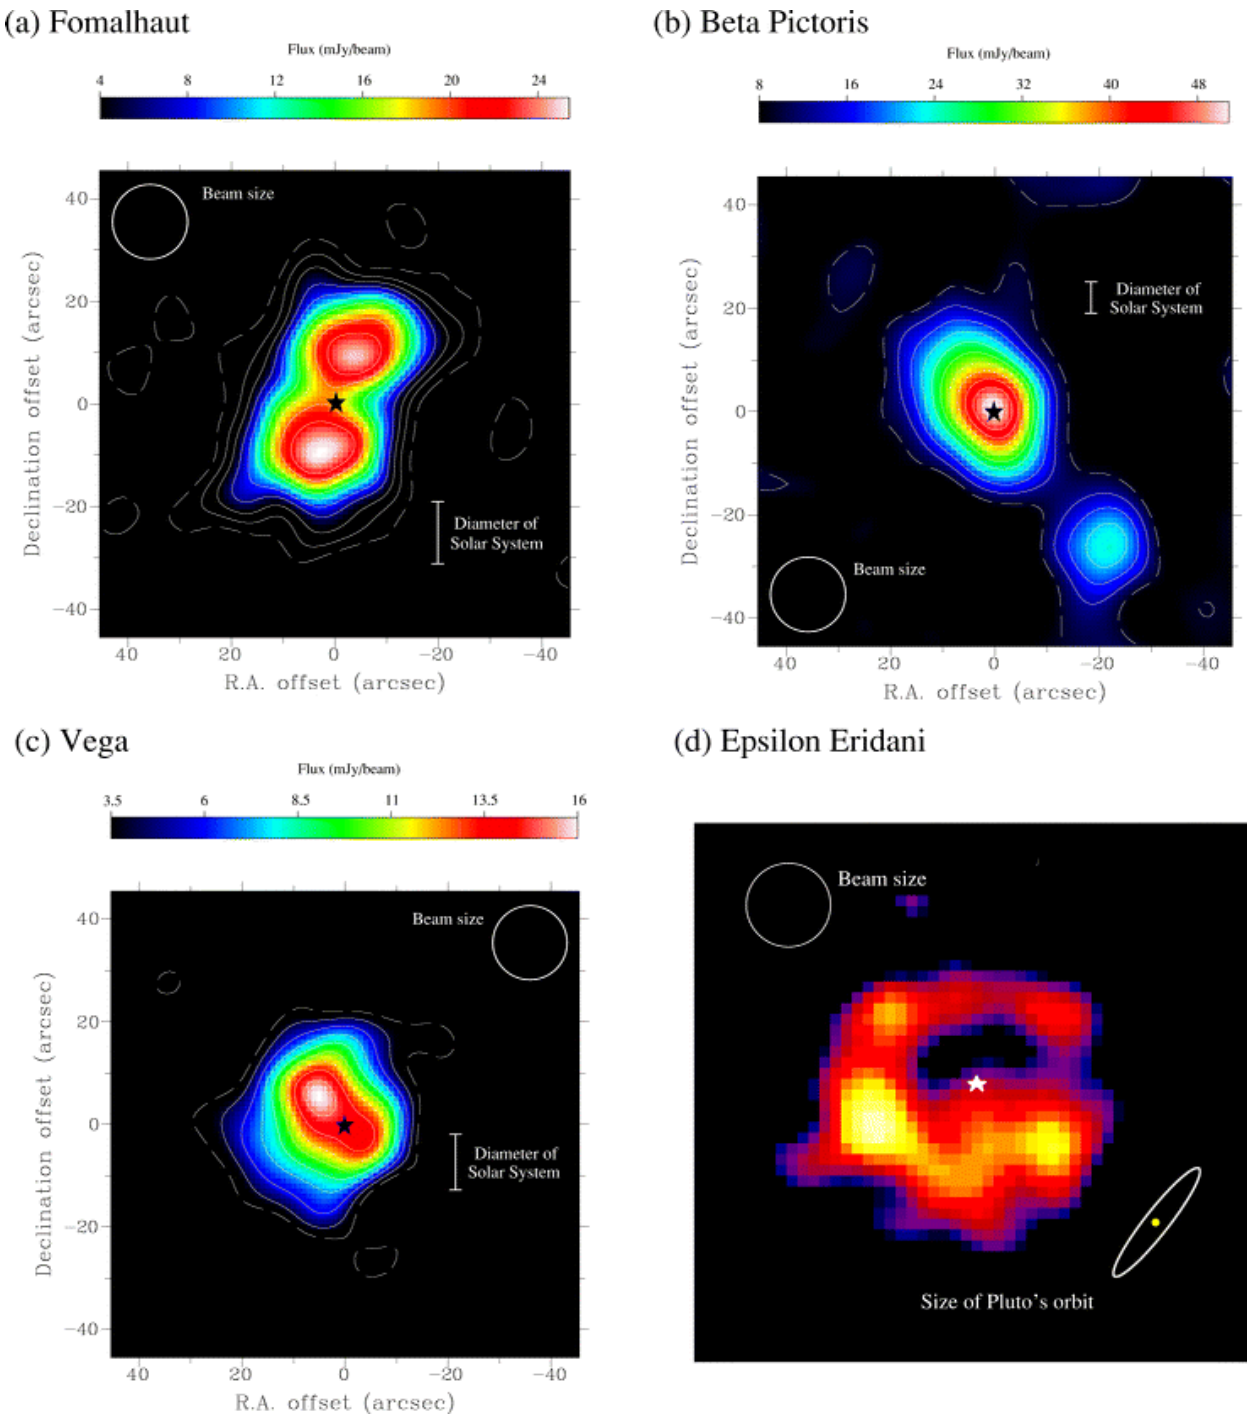

Figure 3. Dust emission around Fomalhaut [(a), upper left], β Pictoris [(b), upper right], Vega [(c), lower left] and ε Eri [(d), lower right] at a wavelength of 850 μm. The images were obtained with the SCUBA bolometer array on the James Clerk Maxwell Telescope. North is up and east is to the left. In each map the star is located at the position of the 'star' symbol. In each panel the diameter of the JCMT beam at half power is shown by the circle. (Images courtesy of W Holland.)

likely then, the preponderance of the gas and dust seen in CS disks around all but the very youngest main sequence stars is the product of destruction of comets, much as the dust component of the ZODIACAL LIGHT seen in the inner parts of our solar system is a product of cometary debris.

First ascent giant stars

The particulate matter in CS disks around main sequence stars may be envisioned as a natural consequence of the star formation process—leftover material that was not

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

incorporated into large objects or, alternatively, particles generated by (partial) destruction of the large objects. In either case, by the time an intermediate mass star evolves off the main sequence one expects very little dust to remain. So, the discovery by IRAS of quite large amounts of dust near a small but not insignificant percentage of ordinary first ascent G and K giant stars came as quite a surprise.

Three models have been proposed to explain the presence of substantial dust near these giant stars: (1) mass ejection; (2) destruction of comets and particulate matter in a Kuiper-belt-like region as the central star increases its luminosity as it leaves the main sequence; and (3) stellar heating of dust in random interstellar clouds that, by chance, lie near some G and K giants. None of these models can be readily reconciled with all existing data. So, at this moment, we do not understand the origin and nature of the dust near G and K giant stars. In addition, gas has never been detected at any of these dusty systems.

Asymptotic and post-asymptotic branch giant stars

Space telescopes have detected strong mid- and far-IR emission from luminous, red giant stars with either carbon-rich or oxygen-rich photospheres. In most cases, the IR emission is produced by dust grains entrained in outflowing winds, i.e., not in a CS disk. But a few of these infrared-bright evolved stars have been found to possess peculiar characteristics of various sorts. For example, a handful of stars with carbon-rich photospheres heat nearby, associated silicate dust grains which formed in an oxygen-rich environment. When measured at such stars, the width of CO rotational lines are typically only one or two km s^{-1} wide and much narrower than lines characteristic of outflowing winds. That is, the narrow linewidths indicate velocities characteristic of orbital motion of gas many hundreds of AU from the stars, rather than gas escaping from the stellar surface.

A plausible, but not yet proven, model for most of these stars with unusual infrared and/or CO spectra is the following. The primary, giant star, is a member of a binary system. When the primary ejects large amounts of mass while it is on the asymptotic giant branch, the gravitational field of the secondary deflects some of this outflowing material into a circumbinary disk, diameter ~1000 AU, which is gravitationally bound to the two stars. The companion star necessary in this scenario has already been detected near some, but not all, of the unusual giant stars. At least a few of the disks show evidence for large scale clumpiness, the nature of which is not now understood.

White dwarfs

A dusty CS disk in orbit around a white dwarf could be detected as excess IR emission. At this moment, in spite of searches at hundreds of white dwarfs, we know of only one, G29-38, that is surrounded by dust grains—these emit strongly at wavelengths between 2 and 20 μm. The origin of the dust is a mystery. Perhaps G29-38 is embedded in a moderately dense interstellar cloud and dust from the cloud has been gravitationally drawn into a disk orbiting the star. Or perhaps there has been some kind of cosmic catastrophe near G29-38, say a collision of two moderately massive objects that has partially shattered them. Or perhaps G29-38 is pulling material off of a nearby but unseen companion. Or perhaps one of any number of other exotic hypotheses.

Properties of the circumstellar dust

Astronomers have expended substantial effort to understand the radiation charactertistics of small dust particles. Early work was on grains in interstellar clouds—such particles typically have submicron dimensions. Observed CS disks have higher densities than interstellar clouds and larger particles are present, either from the sticking together of small particles or from destruction of larger bodies. Perhaps the most interesting astrophysical aspects of the CS dust at a given star are its total mass and spatial distribution. Images such as figure 3 give a large scale picture but, since the dust is heated by the central star, the dust visibility depends on its temperature as well as its spatial location. For example, the sharp cutoff in 850 μm emission outside of the bright 'blobs' seen to the north and south of Fomalhaut is due in part to diminishing dust temperature as well as dust density.

At a given distance from a star the temperature of a dust particle depends on its size relative to the wavelength of the peak of its thermal infrared emission. If the particle is small with respect to the wavelength of its peak IR emission, then such a particle will radiate inefficiently and its temperature will rise above the temperature a large particle would have at the same location. Near this peak of emission, for large and small particles alike, the amount of emission depends sensitively on the dust temperature because of the exponential in the denominator of the Planck function.

So, the appearance of the dust emission at a given wavelength results from a convolution of dust mass and temperature. To derive dust mass it is best to use submillimeter data (as in figure 3) because:

(1) one is on the Rayleigh–Jeans portion of the Planck curve so that intensity is only linearly proportional to dust temperature;
(2) optical depths are small so one is sensitive to all of the mass; and
(3) one can see all of the dust, hot and cold and big and little, at least up to a point.

Particles that are much larger than the wavelength under investigation have relatively low surface-to-volume ratio and the opacity per gram of material

diminishes. Therefore, for measurements at, say, one millimeter wavelength, 'dust grains' larger than about 1 cm in size contribute little to the emission compared to smaller particles, even if most of the mass is in the larger ones.

Hence, submillimeter fluxes can provide only lower bounds to mass in orbit around stars—such observations will not reveal the presence of large objects like comets, asteroids and planets, at least not directly. The existence of such bodies can be deduced indirectly if it can be shown that the detected dust results from breakdown of larger objects. This is likely the case at stars as old as Vega and Fomalhaut. For younger stars like β Pic or the pre-main sequence stars discussed above, we still do not know if the detected dust is left over from the star formation process or is the debris from breakdown of larger objects or some combination of the two.

As an illustrative example, consider the submillimeter flux (F_ν) measured at Earth that is emitted by an optically thin cloud or disk a distance R away.

$$F_\nu = \pi B_\nu 4\pi a^2 Q_\nu n_{gr} V / 4\pi R^2. \quad (1)$$

Here πB_ν is the surface emittance of a single grain per unit area, $4\pi a^2$ is the emitting area of a grain of radius a, n_{gr} is the number of grains per unit volume, and V is the total volume of the cloud. Q_ν is the efficiency with which the grains absorb and emit waves of frequency ν. The total mass (M) of dust in the disk may be written

$$M = \rho N 4\pi a^3 / 3 \quad (2)$$

where N is the total number of grains in the cloud, and ρ is the density of a typical grain. Combining equations (1) and (2) yields

$$M = F_\nu R^2 / B_\nu k_\nu. \quad (3)$$

At submillimeter wavelengths, where $h\nu \ll kT$, the Planck function, B, can be written simply as $2kT/\lambda^2$. Thus, the calculated grain mass is not sensitively dependent on the grain temperature (which is often not well determined).

In equation (3), k_ν is the opacity, that is, the absorption cross section per gram of material at frequency ν. For typical grain materials, the absorption cross section can be much smaller than the total extinction cross section—that is, the grains often have large albedos at wavelengths near a millimeter. The opacity may be written as

$$k_\nu = (\pi a^2 Q_\nu)/(4\pi a^3 \rho / 3) = 3Q_\nu / 4a\rho. \quad (4)$$

This is the absorption per unit mass of dust, whose units are usually given in the literature as $cm^2\ g^{-1}$. Sometimes the opacity quoted in the literature is the absorption per unit mass of dust and gas. To obtain this from submillimeter dust emission (which is the measured quantity) requires an assumption about the ratio of the mass contained in gas to that contained in the dust particles; this ratio is often taken to be 100, the value typical of the interstellar medium. However, in CS disks the gas-to-dust ratio is often much smaller than 100 and it is usually uncertain or unknown, so it is better to quote opacities in terms of dust mass only.

For quite some time, k_ν at wavelengths near one millimeter was uncertain by at least an order of magnitude, resulting in corresponding uncertainty in dust masses. Recent laboratory and theoretical efforts have improved the situation so that now k_ν is probably known to a factor of 3 or so. In any event, one cannot obtain total masses contained in CS disks because objects of dimensions much larger than a few cm are effectively invisible even if they carry most of the mass of the disk (because large objects have such small opacities per gram).

That said, submillimeter fluxes from stars like β Pictoris and HR 4796 that are just arriving on the main sequence indicate total dust masses about 20 times the mass of our Moon. The most common particle sizes lie in the range between 10 μm and a few mm. For older stars like Vega and Fomalhaut total dust masses are 10 times less.

The future

Until the past few years study of circumstellar disks from the ground, with but few exceptions, has not been very rewarding. Analysis of IRAS data obtained over 15 years ago has dominated the field. Recently, sensitive new array detectors at submillimeter wavelengths and in the mid-infrared (10–20 μm) have finally enabled a suite of important ground-based discoveries. At about the same time, the NICMOS near-IR coronagraphic camera on the Hubble Space Telescope obtained stunning images of CS disks around a few young stars.

The coming decade promises great advances in ground-based, airborne, and space-based studies of CS disks. On the ground, millimeter interferometer arrays at high, dry sites in Hawaii and Chile will produce unprecedently detailed pictures of the structure of CS disks. The SOFIA airborne observatory will measure the spatial extent and spectrum of dust emission throughout the far-IR where the CS disks around most Vega-like stars emit most intensely. And from space, the SPACE INFRARED TELESCOPE FACILITY (SIRTF) will enable detection of many new Vega-like systems that emitted too faintly for detection by IRAS. Many such systems may be discovered around stars of solar mass or less that were mostly out of the reach of IRAS.

Dutch Astronomy

The Netherlands has a strong international position in astronomical research, particularly in the fields of radioastronomy, the interstellar medium, structure and dynamics of the Milky Way and other galaxies, stellar and solar physics, and, more recently, high-energy astrophysics. The prominent position is strongly linked to the quality of the research education, to which traditionally much care is devoted. Many graduate students gain postdoctoral positions at premier institutions abroad, or obtain good research positions outside astronomy. As early as the 1930s many astronomers educated in the Netherlands were called to leading positions abroad. For example, between 1970 and 1993 the position of Director General of the European Southern Observatory (ESO) was filled by Dutchmen, Blaauw (1970–5), Woltjer (1976–87) and van der Laan (1988–92) respectively.

Organizational structure

External factors at both international and national levels have important influences on astronomical research in the Netherlands. Intergovernmental organizations like the EUROPEAN SPACE AGENCY (ESA) and the EUROPEAN SOUTHERN OBSERVATORY (ESO) determine, in broad outline, the opportunities for research in the Netherlands, especially in the long-term.

At a national level, the following three organizations determine the research strategy.

The Netherlands Research School for Astronomy (NOVA)

Traditionally, most of the research in the Netherlands is carried out at the astronomical institutes at the universities of Amsterdam, Groningen, Leiden and Utrecht. These institutes are the Astronomical Institute Anton Pannekoek (Amsterdam), the KAPTEYN ASTRONOMICAL INSTITUTE (Groningen), the Astronomical Institute Utrecht and LEIDEN OBSERVATORY. The institutes in Leiden and Utrecht have long historic traditions, having been founded around the middle of the seventeenth century. In 1992, the university institutes federated in the Netherlands Research School for Astronomy (Nederlandse Onderzoekschool Voor Astronomie, NOVA). NOVA's mission is to carry out frontline astronomical research in the Netherlands, and to train young astronomers at the highest international level. Since 1992, all graduate astronomy education in the Netherlands has been concentrated in NOVA. In 1998 the Dutch government initiated a research program, the so-called 'In Depth Strategy', to identify and stimulate national focus points of excellent scientific research. To meet the selection criteria, such focus points were compared with the best foreign institutes in their field of research. In addition they had to have the potential to develop even further and become centers of excellence of world-class reputation. The training of outstanding young scientists was also one of the main objectives of the program. Out of the 34 applications covering all academic disciplines, six national research schools were selected by the Netherlands Organization for Scientific Research (NWO). NOVA was highest ranked among the selected research schools and received a significant grant for the period 1999–2005 to set up an innovative research program (see later for more information). Discoveries with large international telescopes are often made by groups, which have built a novel auxiliary instrument, such as a special purpose spectrograph of a new detector system. In this respect, NOVA initiated Dutch involvement in several instrumentation programs for the ESO Very Large Telescope (VLT) and the VLT Interferometer. For more information the reader should visit the NOVA web site http://www.strw.LeidenUniv.nl/nova.

The Netherlands Foundation for Research in Astronomy (NFRA)

The NFRA was founded in 1949 by Professor JAN HENDRIK OORT to detect radio emission from the Sun and the Milky Way. It was set up as an inter-university foundation under the umbrella of the Netherlands Organization for the Advancement of Pure Research (ZWO, now called NWO). It developed and operated the radio telescopes at Kootwijk in the early 1950s, the 25 m DWINGELOO OBSERVATORY Telescope, which came into operation in 1956, and the WESTERBORK SYNTHESIS RADIO TELESCOPE (WSRT), which was opened in 1970. The Kootwijk and Dwingeloo telescopes produced the first radio maps of the Milky Way in the radiation of the 21 cm line of atomic hydrogen. In the 1970s, the WSRT (at that time consisting of 12 25 m antennas on a baseline of 1600 m, though now 14 antennas on a 3 km baseline) was the largest radio telescope in the world and produced many radio maps of external galaxies to study their kinematical and dynamical behavior.

In the 1980s, NFRA significantly broadened its activities by joining the United Kingdom in developing and operating the ISAAC NEWTON GROUP (ING) OF TELESCOPES on the Canary Island of La Palma, which became operational in 1985. At the same time, NFRA also joined the JAMES CLERK MAXWELL TELESCOPE (JCMT), a 15 m radio telescope in Hawaii dedicated to the observation of electromagnetic radiation in the (sub)millimeter wavelength range. The JCMT collaboration also involved the United Kingdom and Canada. The Netherlands has a 20% share in the ING, as well as in the JCMT. The present arrangements are that the Netherlands will continue to participate in the ING and JCMT until 2009. For the optical instrumentation program, on a national level, the NFRA collaborated with the Kapteyn Sterrenwacht Werkgroep (KSW) in Roden. The KSW was a joint effort of the universities of Groningen and Leiden to focus their technical resources to achieve their contributions to develop and construct instrumentation for the ING. In 1996, the KSW merged with NFRA and moved to Dwingeloo to start an optical/infrared instrumentation group. Their first major project is a collaboration with a French group to build VISIR, the VLT Imager and Spectrometer for the mid-infrared. This instrument will be delivered at the ESO VLT in 2001.

Early in the 1990s, NFRA refocused its activities on the WSRT to upgrade this facility with state-of-the-art multifrequency front-end receivers to improve the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

sensitivity and the flexibility. The upgrade also included a new backend correlator to significantly increase the spectral bandwidth, a pulsar backend (PUMA, largely developed at Utrecht University), new observing modes for VLBI, and filters and software tools to reduce the interference by human communication (TV, radio and mobile phones). The upgraded WSRT was completed by the start of the 21st century. It will allow astronomers to make extensive studies of the formation and evolution of galaxies in the early universe by observing the redshifted 21 cm line of atomic hydrogen in the range of redshifts up to $z = 4$ (or equivalently, back in time when the universe was only 10% of its present age).

NFRA has also been an active partner in the European VLBI Network (EVN). The EVN is a consortium of radioastronomy institutes in 12 European countries and China to jointly carry out radio observations at very high angular resolution (up to milliarcseconds) using very long baseline interferometry (VLBI) techniques. The EVN initiated and supervised the establishment of the JOINT INSTITUTE FOR VLBI IN EUROPE (JIVE). JIVE was set up in 1993 to provide an advanced data processing facility for VLBI in Europe and to support EVN operations. NFRA is the host institute for JIVE. The astronomical operations of JIVE began in the fall of 1999.

In 1995 NFRA started an initiative to seek for world-wide support to develop a next generation radio telescope with a detecting area of the order of 1 km^2 to study the evolution of the early universe and the epoch of the start of galaxy formation. This program is called the Square Kilometre Array (SKA). In order to make such a project financially feasible, one has to remove all moving parts from the telescope. Therefore, NFRA has chosen the technology of phased arrays to achieve flat antennas. All signal processing electronics will be integrated at chip level. This technique will enable the use of software methods for adaptive suppression of external interference. It will also allow for the use of multiple (up to 100 or more) beams on the sky covering the entire visible sky. Current phased array antennas, mainly used in military applications, have narrow spectral bandwidth, while astronomers demand very wide-band systems to study the evolution of galaxies from the early universe to the present epoch. Other countries, like Australia, Canada, China, India and the US, also participate in the technology development for SKA. It is likely that it will take a decade or more to develop the SKA concept before construction will become feasible.

For more information on the activities at NFRA the reader might visit the NFRA website at http://www.nfra.nl.

Space Research Organization of the Netherlands (SRON)

The scientific space research activities in the Netherlands are concentrated in SRON, a foundation within the framework of NWO. Its mission is to initiate, develop, build and use internationally outstanding instruments for scientific research in and from space. The major SRON responsibilities are to develop a national program for scientific space research, to maintain the work program of the SRON institute, which incorporates laboratories in Utrecht and Groningen, and to provide advice with regard to Dutch participation in scientific projects within the framework of ESA.

Many instruments for astrophysical research built by SRON (and its predecessor) in the past, found their place in national satellites, ESA satellites and NASA satellites. Initially, instruments were lifted above the atmosphere by means of sounding rockets and balloons. In 1968 the first Dutch experiment went into space on board an American satellite to measure electrons in cosmic radiation. In the 1970s, a Utrecht experiment did some pioneering work on measuring star spectra in the ultraviolet spectral range. The first completely Dutch satellite was ANS (ASTRONOMISCHE NEDERLANDSE SATELLIET), equipped for photometry in the ultraviolet spectral range and for the detection of x-ray sources. The launch of the European satellite COS-B, designed for a first survey of the Galaxy in gamma radiation, took place in August 1975. Three years later NASA launched the Einstein satellite with a Utrecht x-ray reflection grating on board. It was followed by the Solar Maximum Mission in 1980, with the Utrecht HXIS instrument on board. The second (partial) Dutch satellite, IRAS, and the European EXOSAT (European X-ray Observatory Satellite) were launched in 1983, both containing important scientific contributions from the Netherlands. The data from all these missions have formed a source of pioneering astronomical research for many years.

On 17 November 1995 ESA's Infrared Space Observatory (ISO) was launched. One of the four instruments on board the satellite was built under SRON responsibility: the Short Wavelength Spectrometer (SWS). During a very successful life of 28 months more than 9000 observations were done on stars, planets, galaxies, dust and nebulae. All SWS observations now reside in the Dutch ISO Data Analysis Centre.

SRON provided major contributions to the following astrophysical instruments, which are still operational in space as of early 2000:

- COMPTEL (1991), a gamma-ray detector-spectrometer on board the NASA observatory CGRO;
- the Wide Field Camera for the Italian–Dutch x-ray satellite Beppo-SAX (April 1996);
- the Low Energy Transmission Grating Spectrometer aboard Chandra (formerly called AXAF). Chandra was successfully launched in July 1999;
- the x-ray spectrometer for the ESA satellite XMM, which was successfully launched in December 1999.

Dutch space research specializes in high-energy astrophysics (x-ray research) and low-energy astrophysics (infrared and submillimeter research). For the first decade of the 21st century, SRON has focused its astronomical program on harvesting the scientific data obtained with

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

above-mentioned instruments and on the construction of HIFI, an important instrumental contribution to the submillimeter detection system for the ESA 'cornerstone' satellite FIRST/PLANCK. More information is available at the website http://www.sron.nl.

Focus on three research areas in astronomy and astrophysics

World-wide, one can identify a dozen or so main areas of astronomical and astrophysical research which will flourish in the next decade because of major breakthroughs, driven by the next generation of telescopes which cover the entire electromagnetic spectrum, by the jump in resolution provided by interferometry in the infrared and submillimeter regimes, and by the powerful new computational capabilities for data analysis and theoretical modeling. The Netherlands is very strong in three of these areas. Each area addresses deep questions and together they converge on NOVA's main science theme for the coming decade: the life-cycle of stars and galaxies. These three areas are as follows.

Formation and evolution of galaxies from the distant past to the present epoch

Galaxies contain billions of stars, as well as interstellar gas and dust, and are embedded in dark halos of unknown constitution. Astronomers are able to look back in time by observing galaxies at ever-greater distances. Because light travels at finite velocity, distant objects are seen at a time when the universe was younger. The expansion of the universe causes light to be redshifted, so that the most distant galaxies are those with the highest redshift. How did galaxies form? What processes have occurred between high redshift and the present? Do evolved galaxies contain relics, which are clues to their formation? What are the influences of the environment, of nuclear activity, and of the original large-scale distribution of dark matter? What is the role of massive black holes in galactic nuclei?

In the last few years rapid new developments in instrumentation have provided unique opportunities to find answers to these questions. The Hubble Space Telescope and the ESO Very Large Telescope (VLT) have reached their full potential. Optical telescopes with a diameter of eight or more meters have started to produce exciting data. Dutch astronomers have access to the equivalent of 30% of an 8 m telescope through their membership of ESO. Also, the upgraded WSRT and the JIVE VLBI data processor have led to new research opportunities. As a result, the distant and therefore early universe has now come within observing range. Fast progress is now being made in the study of proto-galaxies and in the large-scale structure of the universe at only one-tenth of its present age.

Birth and death of stars: the life cycle of gas and dust

New stars continue to be born deep inside molecular clouds in galaxies. The birth process leads to a circumstellar disk of gas and dust from which planets and comets may subsequently form. What are the physical processes that lead to these new solar systems, and how do they evolve? How is the chemical composition of the gas and dust involving the major biogenic elements modified during the collapse from the cold, tenuous interstellar medium to the dense protoplanetary material? During the late stages of their life, stars eject nucleosynthetically enriched material into the interstellar medium. How does this material drive the chemical evolution of a galaxy and of the newly formed stars therein? What drives the mass loss, and how does it influence stellar evolution?

The availability of radio telescopes that are able to detect electromagnetic radiation at millimeter and submillimeter wavelengths (like the JCMT) and the success of ESA's Infrared Space Observatory (ISO) have recently led to the possibility of penetrating far into the dusty areas around young and old stars. This is leading to new insights into the physical and chemical processes that occur at the birth and death of stars and into the formation of planets. In this extremely interdisciplinary area new laboratory simulations in the Raymond and Beverly Sackler Laboratory for Astrophysics at Leiden University as well as computer models further contribute to our understanding of the life cycle of gas and dust.

Final stages of stellar evolution: physics of neutron stars and black holes

At the end of its life, a massive star explodes and ejects its outer layers. The stellar core collapses to form a neutron star or a black hole. These are the densest objects that exist, and the ones with the strongest gravitational fields. What are the properties of matter at the extreme density in the interior of a neutron star? What are the observational signatures of black holes? Can we observationally verify the extraordinary predictions of general relativity for the properties of curved space-time near these objects? How do particles and radiation behave near these compact objects? What happens when two compact objects orbiting each other eventually merge? Is this the origin of the most powerful explosions we know, the enigmatic gamma-ray bursts?

Rapid progress is being made in this field as a result of the availability of new satellite measurements with, among others, Dutch instruments, for example in GRO and Beppo-Sax. The significance of x-ray research in extragalactic objects is growing fast. A breakthrough made in mid 1997, to which Dutch researchers made an important contribution, is the insight that the well-known 'gamma-ray bursts' originate in very distant galaxies; it is now certain that the phenomenon involves extremely high-energy acceleration processes, presumably related to the formation of compact objects (neutron stars and black holes) or the fusing of two such objects into a double star. Using the new x-ray observatories XMM (ESA) and Chandra (NASA), to which SRON has contributed important instrumentation, the study of high-energy processes will become possible in the surroundings of

compact objects with unparalleled sensitivity, and spatial and spectral resolution.

There are many connections between the above areas of research. Stars form in galaxies from interstellar material, and at the end of their lives return chemically enriched material to the interstellar medium from which new generations of stars and planets form. The most massive and luminous stars evolve fastest, and leave neutron stars and black holes. This life cycle causes evolution in the stellar population of a galaxy as a whole. Recent technological advances have made it possible to observe this evolution all the way back to epochs when the universe was less than 10% of its present age. Unravelling the history of galaxy formation in the universe, and so understanding the life cycle of stars and galaxies, requires full knowledge of astrophysics and state-of-the-art observations, which are now within reach.

Observing facilities available for Dutch astronomers

Astronomers in the Netherlands have access to the telescopes of the European Southern Observatory (ESO) in Chile, to the UK/NL Isaac Newton Group on La Palma, to the James Clerk Maxwell Telescope (JCMT) on Mauna Kea, to the upgraded Westerbork Synthesis Radio Telescope (WSRT), and to the Joint Institute for VLBI in Europe (JIVE). Together these facilities cover the optical and submillimeter/centimeter wavelength windows. During 2000, ESO's Very Large Telescope, the world's largest optical/infrared telescope, will be completed. ESO plans to combine the light of the four main 8 m telescopes with that of several smaller telescopes to form a near-infrared interferometer (VLTI), which will provide unprecedented spatial resolution. Furthermore, a joint European–US ATACAMA LARGE MILLIMETER ARRAY (ALMA) is planned in Chile, coordinated by ESO for the European side. Initial operations are expected around 2007. The Netherlands will make several major contributions to the VLT and the VLTI. They are: VISIR (see earlier); OmegaCam, a wide field ($1^\circ \times 1^\circ$) optical camera for the 2.5 m VLT Survey Telescope; MIDI, the first instrument on the VLTI to do imaging spectroscopy in the mid-infrared; SINFONI, a near-infrared integral field spectrograph with a large field of view making use of adaptive optics technology. All these projects are collaborations with other institutes elsewhere in Europe, mainly in Germany and France. Visit the NOVA website for further information. The Netherlands is also participating in two technology development studies for ALMA; the NOVA/SRON study for the receiver that will cover the atmospheric window in the 600–720 GHz range, and the NFRA participation in an international study on an advanced correlator. Furthermore, in order to develop knowledge of optical/infrared interferometry and its applications to future astronomy programs, NOVA and ESO initiated a VLTI Expertise Centre (NEVEC) at the Leiden Observatory in 1999.

Dutch astronomers also have access to observing time on a variety of space observatories. The NASA/ESA Hubble Space Telescope, two major new high-energy satellites launched in 1999 (Chandra, XMM), and the Italian–Dutch x-ray satellite BeppoSAX. ESA's submillimeter Cornerstone Observatory FIRST/PLANCK is scheduled for launch in 2007. Together this represents an investment by the world-wide space agencies on the order of US$ 15 billion. Furthermore, the databases obtained with ESA's astrometric satellite Hipparcos and infrared satellite ISO will, at least for the next decade, contribute to exiting new results.

Dwarf Elliptical Galaxies

DWARF SPHEROIDAL GALAXIES were first identified by Shapley, who had noticed two very diffuse collections of stars on Harvard patrol plates. Although these systems had about as many stars as a GLOBULAR CLUSTER, they were of much lower density, and hence much larger radius, and thus were considered distinct galaxies. These two, named Fornax and Sculptor after the constellations in which they appear, are in fact satellites to the MILKY WAY and are part of a family currently numbering nine that orbit the Galaxy. Studies by Baade and others showed that the stellar populations are old, based on the presence of RR LYRAE STARS and the apparent lack of star formation regions, prompting a question of link between these galaxies and the ELLIPTICAL GALAXIES. The galactic dwarf spheroidals are themselves part of a larger class of galaxy called dwarf ellipticals (dE), which extend in luminosity from that of the faintest dwarf spheroidals ($M_V = -9$) to around $M_V = -17$, a good example being NGC 205. These galaxies are referred to as 'spheroidals' by some authors. The basic isolating characteristics of the class are low surface brightness and smooth light distribution. The radial light distributions tend to be exponential, which they have in common with IRREGULAR and SPIRAL GALAXIES and which distinguishes them from the ellipticals, which have more of a power-law light profile. Also, the surface brightness (either central or average value) decreases with decreasing luminosity, whereas for ellipticals surface brightness increases with decreasing luminosity. There is a range of luminosities for which both dwarf ellipticals and ellipticals exist—the difference in the types is then best demonstrated by the remarkable differences in structure between that of NGC 147, a dwarf elliptical, and M32, an elliptical, both of which are companions to M31 and which have similar luminosities (figure 1).

dEs are very common. In the LOCAL GROUP, there are 19 known (nine around M31, one unattached to a large galaxy, and the nine of the Milky Way already mentioned). The nearby group of M81 has 12 known. The largest collections of dEs, however, are found in the rich clusters. Virgo, for instance, has had over 400 dEs cataloged to the relatively bright luminosity of $M_V = -13$, although the dwarfs as a population contribute less than 10% of the total light of the cluster. There is some indication that the relative number of dEs to giant galaxies in a group goes up as the number of giants increases. The luminosity function of dEs was shown by Sandage, Binggeli and Tammann to have an exponential form, thus entailing the exponential part of the Schechter function which represents the luminosity function of all galaxies. The slope of this function in CLUSTERS OF GALAXIES shows significant variations among clusters studied, with the interesting result that clusters with large cD galaxies have proportionately fewer dE galaxies (slope $\alpha \sim -1$) than do those clusters without such a dominant galaxy ($-1.4 \geq \alpha \geq -2.0$). The conclusion here may be that cD halos are formed by the disruption of dwarfs, although the mechanism for doing so is unidentified, and it is as likely that the problem needing explaining is actually the preponderance of dEs in non-cD clusters. The three dimensional shapes of dEs appear not to be disks, despite their exponential light profiles; rather, the flattening distributions indicate spheroidal or ellipsoidal shapes because of the lack of very flat systems. The lack of nearly circular galaxies argues against the galaxies being oblate, and although prolate systems are permitted by the data, it is most likely that, as a group, these galaxies are triaxial.

Because of the intrinsic faintness of these galaxies, there is not a surfeit of kinematic information about them, although what is known has proved to be crucial to the study of DARK MATTER IN GALAXIES. Studies of the velocities of individual stars in the galactic dwarf spheroidals have shown that the least luminous galaxies (UMi and Draco) have velocity dispersions around 10 km s^{-1} similar to the dispersions found in the brightest galactic dwarf spheroidal, Fornax, which is nearly 100 times more luminous. The high dispersions result most simply in total M/L values of order 100 for the faint dwarfs, and since the stellar M/L values are order unity, there is thus strong evidence for unseen matter. Modeling attempts to explain the large velocity dispersions by interactions and disruptions with the Milky Way have largely been unsuccessful, because these interactions, while disturbing the structure of dwarfs galaxies, do not significantly alter the central velocity dispersions. More detailed structural models of the galaxies, in which dark matter halos are included along with the observed luminous matter distribution, have confirmed the large M/L ratios and also shown that the central densities of dark matter can be very high, near 1 $M_\odot$ pc^{-3}, much larger than the density of visible stars.

Spectral observations in integrated light of more distant galaxies have further shown that the dEs are slow rotators and are in general not rotationally flattened, thus placing them on common ground with the large ellipticals, and making them different from the low-luminosity ellipticals, which are rotationally flattened. The galactic dwarf spheroidal UMi, which is quite flat in projection ($e = 0.6$), has also been shown to have little rotation, the data coming from individual constituent stars in this case. The velocity dispersions obtained in integrated light of luminous dwarf ellipticals tend to indicate normal M/L ratios; i.e. the central areas are not dark matter dominated.

A salient feature in nearly half of the luminous dEs is the presence of a distinct nucleus. The most widely known nucleus is surely that of NGC 205, although this nucleus is in fact quite different from those of most other galaxies in that it is a young star cluster, part of the star formation event first noticed by Baade. The nuclei in other dEs appear to be the same age as the surrounding galaxy. For a small nucleus, it can appear simply as a star cluster, occasionally miscentered in the host galaxy; in the cases where the nucleus is large, it tends to blend in with the structure of the surrounding galaxy rather

than appear as an imposed star cluster. Their luminosities range upwards to $M_V = -12$, which is somewhat brighter than the brightest globular clusters known anywhere. The presence of a nucleus is weakly correlated with a number of other properties. They occur more frequently in more luminous galaxies. They occur more often in rounder galaxies. In clusters, the nucleated galaxies tend to be more concentrated as a group than do non-nucleated galaxies. Also, the nucleated galaxies tend to be redder than non-nucleated galaxies, although there is little color difference between the nucleus and the surrounding stars. None of these tendencies yet points to an origin of the nuclei, however, other than to support the obvious idea that the nuclei are secondary star formation events, where gaseous material fell to the center of a newly formed galaxy and built up a region of high stellar density. HST images of a nearby nucleus (which contains nearly 5% of the total galaxy luminosity) show a central density as high as that found in galactic globular clusters (figure 2).

Like all types of galaxies, dEs contain globular clusters. The presence of them is directly related to the host galaxy luminosity, and the scaling factor appears to be more like the ellipticals with a relatively high number of clusters per unit luminosity (4 per unit $M_V = -15$), rather than like the spirals which are cluster poor. The faintest known galaxy with globular clusters is still Fornax, which has 5. Colors and metal abundance measures of dE globulars indicate that they are more metal poor than the surrounding halo in the mean; a similar situation is found in ellipticals.

Ideas that the stellar populations are similar to those of globular clusters (i.e. uniformly old) have had to be modified, first because of the indirect indicators of young age such as the presence of anomalous Cepheid variable stars, the second parameter problem (a red horizontal branch in a metal-poor system) and upper asymptotic giant branch stars, and later more directly by color–magnitude diagrams (particularly of Carina), which show multiple main sequence turnoffs, indicating several discrete epochs of STAR FORMATION. Many of the Local Group

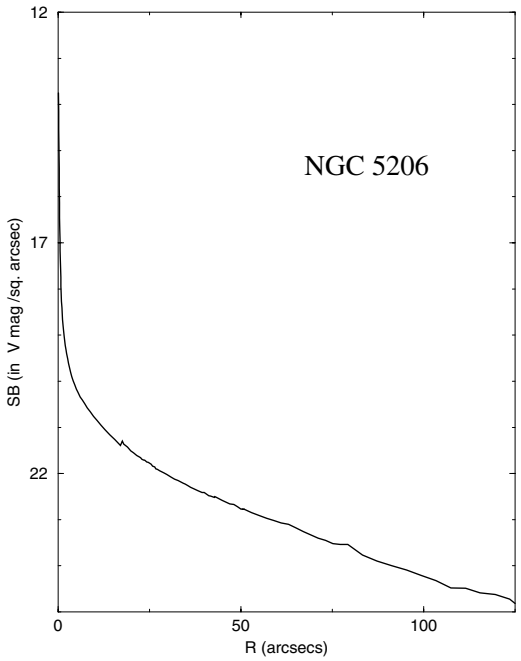

Figure 2. Radial light profile of NGC 5206

dwarf spheroidals show such evidence for star formation more recent than 10 Gyr. Direct evidence for current star formation among Local Group dEs is found only in NGC 185 and 205, however. More distant galaxies also show some signs of recent star formation, in that the integrated colors show large variations among galaxies of similar luminosity; some colors are bluer than can be explained by low metallicities. It is apparent that star formation in dEs is a more complex thing than in globular clusters. The acquisition of more star formation material can explain some cases, but others require self-regulation of star formation, via stellar winds perhaps. Galaxies such as the Phoenix dwarf and LGS3 are thought to be transition objects, in which star formation is about to end,

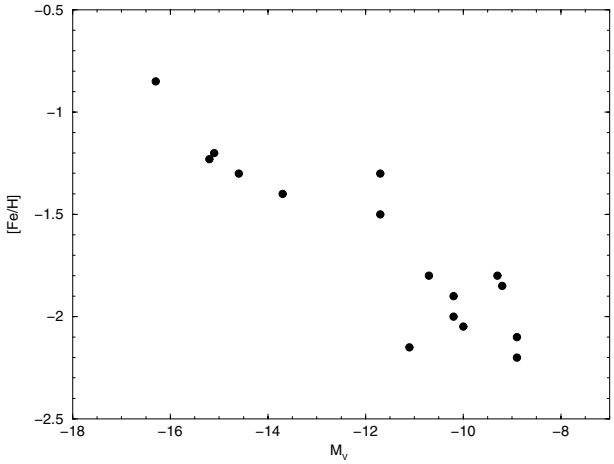

Figure 4. Relation between luminosity and metallicity for dwarf ellipticals.

after which time the galaxy would take on the appearance of a dE. Studies of all the dwarfs in the Local Group (including the irregulars) show that dwarf elliptical star formation histories merge smoothly into those of DWARF IRREGULAR GALAXIES. A useful summary might be that stars began forming in dwarf ellipticals 15 Gyr ago, but that star formation may have ceased only a few Gyr ago.

dEs as a class have a number of remarkable relations between observed properties. As mentioned above, the central or mean surface brightnesses are directly related to the total luminosity, over a range of about 8 magnitudes (figure 3). The central values used for this relation are extrapolated values, so that any nuclei present are ignored. This relation is not tight, however, and some have even doubted that it exists, noting that surface brightness selection effects in galaxy searches would tend to produce such a relation. The central surface brightnesses of these galaxies are of course well below that of the night sky. However, more recent deep searches, while finding the very interesting large (and hence luminous) low-surface-brightness galaxies, have not found them in the abundance that would fill the surface brightness–luminosity plane uniformly. Thus, it seems likely that while large deviations from a relation do exist, there is a preferred or dominant relation. (One has to be careful to distinguish large, low-surface-brightness dwarf elliptical galaxies, with M_V fainter than -18, from the large, low-surface brightness disk galaxies, such as Malin I.) A second relation is that of mean stellar metallicity (Z) and total luminosity (L) (figure 4). The metal abundances used in this relation are those found from color–magnitude relations, and thus the galaxies measured so far are all at least within the reach of HST. Over a range of 8 magnitudes, the metallicity changes by 1.4 dex (a factor of 25, $Z \propto L^{0.4}$), and the relation is fairly tight. A question then arises: with two relations relating three parameters, L–Z, and L–SB, one tight and one not so tight, is the relation between SB and Z tight or not? That is, is the true parameter that dictates mean metallicity during galaxy formation the galaxy luminosity (total mass), or rather the surface brightness (surface density)? Observations of one large low-surface-brightness galaxy in the M81 group provide the answer here. This galaxy lies well off of the main SB–L relation, and also lies well off of the main SB–Z relation. However, it does lie on the L–Z relation formed by Local Group galaxies. Thus it is luminosity that dictates the metallicity. It is interesting that in the faintest dwarfs, while the luminous matter is a small fraction of the total mass, it is the luminous matter that dictates the metallicity.

The existence of the metallicity–luminosity relation and the surface brightness–luminosity relation as well as the complex star formation histories have provided an impetus for searches for theories of how these galaxies formed. Formation ideas are varied, from the detritus models wherein the small companion dE galaxies are the leftover material of large galaxy formation, to formation in tidal tails of interacting galaxies, to that of Babul and Rees which is a more *ab initio* scheme. Babul and Rees have shown that the collapse of weak density perturbations can be delayed because of the photoionizing effects of the intergalactic UV radiation field at redshifts greater than 1. Thus star formation in dwarf galaxies may have begun relatively late and may have resulted in that class of galaxies being excessively bright at intermediate redshifts, perhaps leading to the excess number of blue galaxies apparent at those redshifts. Larson showed that the more massive dwarf precursors were better able to retain gas (which otherwise would have been lost via supernova explosions) and hence had longer-lived star formation epochs, resulting in higher central densities and higher metallicities. Since gas loss in self-gravitating systems cannot explain both the observed form of the decline in metallicity and surface brightness with luminosity in dEs, Dekel and Silk developed a model which included the presence of dark matter, wherein mass loss from

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

supernova winds becomes important at a threshold value of mass and allows both stated conditions to be met. Being derived from hierarchical scenarios, the dwarfs should also predominate in areas of low density (i.e. voids), something for which there is much counterevidence for.

There are obvious connections between dEs and star-forming dwarfs (dIrrs)—low surface brightness, low metallicity, low luminosity and even similar flattening distributions. However, in detail there are problems with the idea that dEs are simply the extension of dIrrs—those galaxies that ran out of star forming gas first. As a class, dwarf ellipticals are smaller than dIrrs—there are many more large dIrrs than dEs. Thus it is hard to obtain all of the dEs by stopping the star formation and allowing the dIrrs to fade—the length scales would be wrong. (It would be possible to obtain some fraction of the dEs this way of course.) It has been difficult to compare the metallicities of dEs ([Fe/H] in general, from giant branch locations) with those of dIrrs ([O/H] in general, from ionized gas measures) to check the idea that at the same luminosity, corrected for fading for dIrrs, the two types have similar metallicities. Preliminary work does show that it is marginally possible for the observed L–Z relation of dEs to have come from that of dIrrs, but the amount of luminosity fading required is excessive. It is certainly true that dEs and dIrrs come from related progenitors, although the precise parameters separating those families is not yet known.

Dwarf Galaxy

A small galaxy with a very low mass and luminosity. Dwarf galaxies may be elliptical or irregular in shape but, in either case, are usually sparsely populated with stars, have low surface brightnesses, low overall luminosities, and consequently are hard to detect. It is usually possible to look straight through a dwarf galaxy. Dwarf ellipticals are populated by old stars and contain little, if any, gas, whereas dwarf irregulars contain younger stars and substantial quantities of gas. Dwarf elliptical galaxies, which typically contain from a few hundred thousand to a few million stars, have diameters of a few thousand light-years and luminosities ranging from about 10^5 to about 10^7 solar luminosities, are probably the most abundant species of galaxy in the universe. They are denoted by 'dE' in the Hubble classification scheme. Dwarf irregulars, which appear to be less abundant than dwarf ellipticals, contain from about 10^6 to 10^8 (or, exceptionally, up to about 10^9) stars. The smallest galaxy known is GR-8, a dwarf irregular with a diameter of 1000 light-years.

Dwarf Irregular Galaxies

Dwarf irregular galaxies at optical wavelengths are small, faint and appear to be unstructured and irregular in shape. They are typically gas-rich, metal-poor systems, with varying levels of STAR FORMATION occurring in a haphazard manner across the galaxy. Their structure does not normally include any distinctive features, such as spiral arms or nuclei, and their kinematics seems to be dominated by random motions or relatively slow solid-body rotation. There is not an extremely precise definition of what is a DWARF GALAXY and what is not, but the most typical demarcation between a dwarf galaxy and a larger ('normal') galaxy is that dwarfs are typically fainter than an absolute B-band magnitude $M_B = -16$. This is not a strict rule, as the Small Magellanic Cloud (with $M_B = -17$) is often considered to belong to the class of dwarf irregular galaxies. The lumpy irregularities in the optical morphology of dwarf irregular galaxies are due to randomly distributed star formation regions, which may be individually quite bright, but the overall surface brightness is typically extremely low ($\Sigma_0 \sim 23$–25 mag arcsec^{-2}). Because this type of galaxy is so numerous and they can easily vary in brightness quite dramatically owing to increased star formation rates, there is strong evidence to suggest that they are cosmologically important population of galaxies.

There are several classes of dwarf galaxy, not only dwarf irregular galaxies, and the difference between dwarf irregular galaxies and other classes of dwarf galaxy, such as 'blue compact dwarf' galaxies, 'dwarf spheroidal' galaxies and 'dwarf elliptical' galaxies, is often a question of semantics and has not always been precisely defined. These types of dwarf galaxy on average fall into the same low surface brightness class, but differ in their current rates of star formation. Blue compact dwarf galaxies have one or more compact, high star formation rate regions (e.g. NGC 1705, NGC 1569, VII Zw403). DWARF SPHEROIDAL GALAXIES, on the other hand, currently have no ongoing star formation, and no detectable gas, but they can show evidence of having had a complex star formation history, including one, or more, distinct episodes of star formation (e.g. Carina, Leo I, Sculptor). There are also a small number of what appear to be transition objects, which have extremely low rates of current star formation, but with evidence of more active star formation in the recent past (e.g. Pegasus, Phoenix, Antlia). The existence of these transition objects leads to the hypothesis that dwarf spheroidal, irregular and blue compact galaxies are all the same type of object, observed at different evolutionary phases. DWARF ELLIPTICAL GALAXIES (e.g. M32, NGC 147, NGC 185) usually have evidence only for a fairly old stellar population, and it is not entirely clear that they can fall into the same global scheme as the other types of dwarf galaxy suggested above.

Dwarf irregular galaxies are the most common type of galaxy in the region surrounding our own Galaxy, the so called LOCAL GROUP. In a recent census, 22 out of 41 galaxies within the Local Group can be classified as dwarf irregular type galaxies. Similar results, showing the dominance of dwarf irregular populations, can also be seen for other nearby groups of galaxies (or often called CLUSTERS OF GALAXIES), such as Virgo and Fornax. There are also indications from redshift surveys that the universe as a whole is dominated by small irregular type galaxies. It is of historical interest to note that the first object to be '... definitely assigned to the region outside the Galactic system ...' (i.e. to be extragalactic) by Edwin Hubble in 1925 was NGC 6822, one of the nearest examples of a dwarf irregular galaxy. Pioneering work by Walter BAADE, starting in 1944, taking the first steps in understanding galaxy evolution, was based on studies of the resolved stellar populations in dwarf galaxies. Baade noted that the dwarf elliptical galaxies he looked at contained only red stars, namely old stars (which he called population II), and dwarf irregular galaxies contain red and blue stars, which indicate a younger population (which he called population I). He further noted that while an exclusively old population has been observed, a young population was never seen without an old underlying, fainter, population of red stars, which is called 'Baade's Sheet'.

Because of their small size and low surface brightness dwarf irregular galaxies can be very hard to detect, even in the Local Group, and to the present day we are still finding new dwarf irregular galaxies (e.g. Antlia in 1997, by a group from Cambridge, England). The first major survey of these faint and often unregarded smudges on photographic plates was undertaken by the Swedish astronomer Holmberg, in 1950 in the M81 and M101 galaxy groups. A further extensive specific search for field dwarf galaxies was undertaken by van den Bergh in 1959 in Canada (the DDO catalogue). Of the present-day dwarf irregular members of the Local Group 50% have been found since 1971, and we cannot rule out that we will find many more extremely low surface brightness objects in the Local Group.

The distribution of neutral hydrogen (H I) gas in dwarf irregular galaxies is very clumpy and irregularly distributed and is frequently much more extended than the optical emission. There have been very few cases in which molecular gas has been detected. Molecular gas, typically, means carbon monoxide, CO, which is relatively straightforward to detect and is considered to be a tracer for the presence of molecular hydrogen, H_2, which is the most important constituent in the star-formation process. Given the importance of molecular gas to the star-formation process it must exist in these galaxies, as we see young stars. It is possible that the extremely low metallicity of dwarf irregular galaxies makes the molecular gas more difficult to detect, because the relative fraction of CO to H_2 molecules is much smaller than in our Galaxy.

Dwarf irregular galaxies are also so-called 'metal-poor' galaxies. This means that the abundance of 'metals', namely elements with atomic numbers greater than 2, relative to the abundance of hydrogen is much lower

than is observed in our Sun (the solar abundance). The metallicity of dwarf irregular galaxies ranges between 2.3% of the solar value (e.g. Leo A) and around 10% of the solar value (e.g. IC 1613). The typical elements observed to determine the metallicity of nearby galaxies are carbon, oxygen and nitrogen, which are detectable in optical and UV emission lines in currently star-forming regions (so-called, H II regions), and iron has been measured in spectra of individual stars of various ages. The extremely low abundances of metals relative to hydrogen, typically in the range 2–15% of solar neighborhood values, can be taken as a sign either of youth or of a sporadic star formation history, or a combination of both.

The star formation history, or luminosity and color evolution, of dwarf irregular galaxies shows evidence of not having been a smooth function of time. That is to say, they have been subject to sporadic increases in the average rate of star formation, so-called 'bursts' of star formation. These bursts may make a dwarf irregular galaxy look much more like a blue compact dwarf galaxy. Evidence for these bursts of star formation comes both from the direct observations of the resolved stars (the stellar population) in nearby dwarf irregular galaxies, a census of which gives information about the star formation history that has created the currently seen age and metallicity distribution, and also from studies of the luminosity and colors of much more distant, late-type galaxies seen at intermediate redshift (so-called faint blue galaxies).

It is possible to derive very accurate star formation histories from resolved stellar populations going back to the oldest star formation episodes in a galaxy. Low-mass stars can live a very long time, and thus leave a longstanding fossil record which can be directly interpreted as the star formation history of a galaxy through the entire history of the universe. Current evidence shows that every dwarf galaxy in the Local Group has had a different star formation history from every other. Dwarf irregular galaxies typically appear to contain old populations, as seen from the red giant branch stars, but this has only been unequivocally proven from the detection of RR LYRAE STARS in one or two cases (e.g. IC1613). Dwarf irregular galaxies thus not only have irregular morphology but also have had irregular star formation histories, dominated by short 'bursts' of star formation, rather than a more or less constant rate of star formation with time (as for spirals) or an epoch of formation a long time ago (as for ellipticals). This is consistent with what we know about blue compacts and dwarf spheroidals as well.

Nearby dwarf irregulars are currently forming stars at an extremely low rate, and although this low rate may be more or less a constant underlying rate, through time every so often this rate does increase. When this happens it is possible that a dwarf irregular galaxy would then be classified as blue compact dwarf galaxy, and if this rate ever goes to zero they would be dwarf spheroidals.

The surveys to study the properties of the very distant, so-called 'faint blue galaxies' seen in all deep images of the sky have come to the conclusion that the majority of these objects are at intermediate redshifts and are late-type STARBURST GALAXIES. An analysis of the number of faint blue galaxies in deep surveys, combined with their luminosity and color variations, gives an indication of how short and how intense these bursts of star formation must be for us to detect the number of faint blue galaxies that we do. This type of analysis suggests that they are quite small and undergo extremely short extremely intense bursts of star formation. Detailed imaging of these objects from the Hubble Space Telescope shows a large majority to be irregular in shape. Thus what is known about these very distant, very faint but very numerous faint blue galaxies is perfectly consistent with what we can assume about the present-day characteristics of the dwarf irregular galaxies we see and can study in great detail in the nearby universe and Local Group. Dwarf irregular galaxies are thus a very important link between the nearby universe, which we can study relatively easily, and the most distant objects in the universe, GALAXIES AT HIGH-REDSHIFT, which we can never hope to be able to study in the same detail as Local Group galaxies.

Dwarf Spheroidal Galaxies

Our galaxy, the MILKY WAY, is surrounded by a swarm of dwarf galaxies each composed of 100 000 to billions of stars. Many of these galaxies are easy to see; for example, the MAGELLANIC CLOUDS are visible to the naked eye for observers in the Southern Hemisphere. Many of the dwarfs are far more difficult to spot; some of these were discovered telescopically in the nineteenth century. One class of nearby dwarf galaxy eluded discovery for even longer. In the late 1930s, Harlow Shapley and Walter Baade reported the discovery of a new type of 'star system' in the constellation Sculptor (figure 1). Barely visible on their original plates, this new object was the first example of a dwarf spheroidal (dSph) galaxy ever found. It is now known to be one of nine such galaxies orbiting the Milky Way.

By convention, the nearby dSph galaxies are usually named after the constellation in which they are located (see table 1). The nine dSph galaxies closest to the Milky Way are all very likely gravitationally bound to our Galaxy. The remaining dSph galaxies listed in the table reside within the LOCAL GROUP of galaxies, and all but one are satellites swarming around the nearby the ANDROMEDA GALAXY. In recent years dSph galaxies have been discovered in large numbers within other nearby GROUPS OF GALAXIES and GALAXY CLUSTERS. When these numbers of known dSph galaxies are extrapolated to the universe as a whole, it becomes apparent that dSph galaxies are by far the single most common type of galaxy by number.

If dSph galaxies are so common, how did they elude discovery for so long? Even in the darkest, most remote sites on Earth, the sky glows faintly with optical radiation. This light comes mostly from atomic and molecular emission from the upper parts of our own atmosphere, from sunlight reflected off dust scattered throughout the solar system and within our atmosphere, and from individually invisible, but very numerous faint galaxies and stars. Most galaxies have surface brightnesses comparable to that of the night sky; that is, the total light they emit over the total area of the galaxy as seen in the sky is comparable to the amount of light the sky itself emits. These high surface brightness galaxies—SPIRAL and ELLIPTICAL GALAXIES—are the ones most commonly pictured in popular astronomy books. They represent what most people think about when they imagine a 'typical' galaxy. In contrast, dSph galaxies have far lower surface brightnesses, glowing faintly with a surface brightness as low as only 1% that of the night sky. These galaxies are the closest examples of true LOW SURFACE BRIGHTNESS systems.

Finding such ghostly objects would be similar to spotting a 40 W lightbulb in front of a large searchlight or discerning a 1 m rise in a 100 m tall plateau from far away. Sculptor was found in the 1930s only because it is one of the brightest nearby dSph galaxies, it is located in a particularly dark part of the sky, and many photographic plates were available by that time to confirm its discovery. Many of the most recently discovered dSph galaxies were not found by eye, but from sensitive electronic measurements of photographic images of large regions of the sky. Because they are so difficult to spot, it seems certain that many more nearby dSph galaxies remain to be discovered.

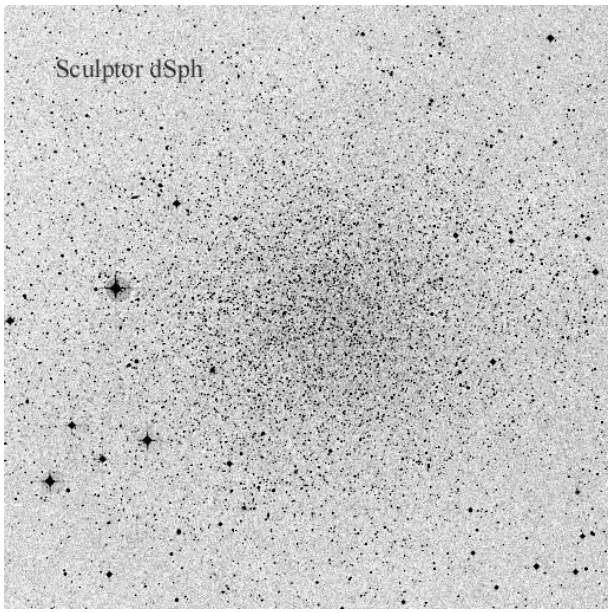

Figure 1. An negative image of the Sculptor dSph galaxy, a nearby satellite of our home Galaxy, the Milky Way. Sculptor is located about 220 000 light-years away and the galaxy is clearly resolved into individual faint stars as seen in the picture. The bright stars in the image are most likely located in our Galaxy somewhere between us and Sculptor. Some of the fainter objects are background galaxies far behind Sculptor. For comparison, the full Moon would easily fit within the field of view shown in the figure. This picture is used by permission from the digitized Southern Sky Survey from Space Telescope Science Institute; the original plate was obtained at the Anglo-Australian Observatory with the UK Schmidt Telescope.

Global properties of dwarf spheroidal galaxies

As their name implies, dSph galaxies are among the smallest, least luminous galaxies known. Ursa Minor, for example, shines with a total luminosity of about 300 000 times the luminosity of the Sun. By comparison, the Magellanic Clouds—dwarf companions of our Milky Way—emit as much light as 2 billion Suns. Even some of the Milky Way's GLOBULAR CLUSTERS emit more light than the faintest dSph galaxies. Most dSph systems show a centrally concentrated structure with a core region of nearly constant, but extremely low, surface brightness. The outer parts of dSph galaxies slowly fade into the night sky; in many cases, no well-defined outer boundary can be measured. The central cores range from 1000–3000 LIGHT-YEARS in diameter, while the ill-defined outer boundaries typically extend 3–10 times further out; the dimensions of the Local Group dSph galaxies (see table 1) are representative. The ultra-low core surface brightnesses

Notes:* Name of Galaxy about which the listed dwarf orbits. And = the Andromeda galaxy; MW = the Milky Way; none = indicates that the galaxy appears to be unbound to any identified parent galaxy.

and small sizes are the features that principally distinguish dSph systems from all other classes of galaxies.

Many dSph galaxies also exhibit well-defined central nuclei that are far more compact than the galactic cores. In many cases, the optical appearance of the nuclei resemble that of large globular clusters. Nuclei in dSph galaxies are most common in the more luminous systems, but, even among the brightest dSph systems, not all possess nuclei. Only one dSph galaxy in the Local Group unambiguously contains a nucleus: NGC 205, a companion of the Andromeda Galaxy. These galaxies range in shape on the sky from nearly circular to highly elliptical. In terms of the HUBBLE CLASSIFICATION system, they range from E0 to E7. It is not unusual for the core of a given galaxy to exhibit a different elliptical shape and orientation than the outer region of the same system (see figure 3 of NGC 205 in the entry the Local Group).

Most of the radiation from dSph galaxies is emitted in the form of starlight in the optical portion of the ELECTROMAGNETIC SPECTRUM. The lack of strong emission lines, infrared, or radio radiation suggests that these galaxies are generally devoid of an interstellar medium composed of gas or dust floating freely between the stars. Recent observations have revealed a possible, though complicated, relation between some nearby dSph galaxies and clouds of neutral hydrogen gas visible only at radio wavelengths. These galaxies also emit very little light that can be attributed to extremely young stars or star-forming regions. This suggests that dSph galaxies are currently dormant systems that formed most of their stars more than about 1 billion years ago.

Nearby dwarf spheroidal galaxies

Because most distant dSph galaxies appear as featureless smudges of light, we must turn to the closest dSph satellite galaxies within the Local Group to try to understand the true nature of these little, but extremely common, systems. At the time of the initial discovery of Sculptor by Shapley and Baade, it was clear that dSph galaxies were composed of stars similar to those found in globular clusters. Moreover, dSph galaxies and globular clusters were the only sorts of objects known to inhabit the outermost regions of the halo of our Galaxy. These features and the simple structure of both types of star systems seemed to indicate that dSph galaxies were simply puffed up versions of otherwise normal globular clusters.

This belief persisted for many years, but in time enough evidence accumulated to begin to suggest that something far more complicated was going on within dSph galaxies. The Ursa Minor galaxy, for example, appeared to be so extended that it could not possibly be gravitationally bound. The implication was that we were witnessing the disruption of this dwarf galaxy as it passes close by the Milky Way. The problem with this was that independent calculations of the tidal forces suggested that Ursa Minor was sufficiently far from the Milky Way that it should not yet be falling apart. As astronomers began to carry out detailed studies of the individual stars in the closest dSph systems, they confirmed that the stars in dSph galaxies are deficient in heavy elements compared with the Sun. Oddly, the global properties of the stars in color–magnitude diagrams of dSph galaxies did not confirm these low element abundances. This seemingly contradictory behavior is known as the second

parameter problem and it is present in nearly every dSph system. These dwarfs also contain luminous CARBON STARS and unusual VARIABLE STARS that are not found in globular clusters.

In the early 1980s the first studies of dSph galaxies employing modern electronic detectors and large-aperture telescopes revealed two unexpected features that helped explain these puzzles. The first was that the stars with individual dSph galaxies appear to be moving far too fast relative to one another to remain bound within such small galaxies. That is, if we estimate the mass of each galaxy based on the number of visible stars, we find that every one of these galaxies appears to be disintegrating before our very eyes, not just Ursa Minor! Because this seemed highly improbable, the assumption that we see all the mass in dSph galaxies was questioned. One alternative model is that the galaxies are much more massive than expected from their visible matter because they contain DARK MATTER. Dynamical models that include dark matter do adequately explain the internal motions of the stars in all dSph systems. In the most extreme cases, only 1% of the mass of the galaxy is visible. The rest of the mass is composed of dark matter whose nature, unfortunately, remains a complete mystery. If this is true, dSph galaxies have the largest proportion of dark mass of any known type of galaxy and can therefore claim to be the 'darkest' galaxies known. Curiously, dark matter models also suggest that no dSph galaxy has a mass less than about 10 million times the mass of the Sun.

The second revolutionary observation proved that, unlike globular clusters, dSph galaxies contain significant numbers of 'intermediate-age stars'. Thus, these galaxies appear to have formed stars over a large fraction of the lifetime of the universe while globular clusters generally formed nearly all of their stars very soon after the universe first formed. Modern studies of nearly all the nearby dSph galaxies reveal evidence of a complicated star formation history, each galaxy being different from all the others much like the ages of children may differ greatly from family to family even within a small town or neighborhood. How and why individual dSph galaxies have been able to support extended and episodic star formation histories remains unclear.

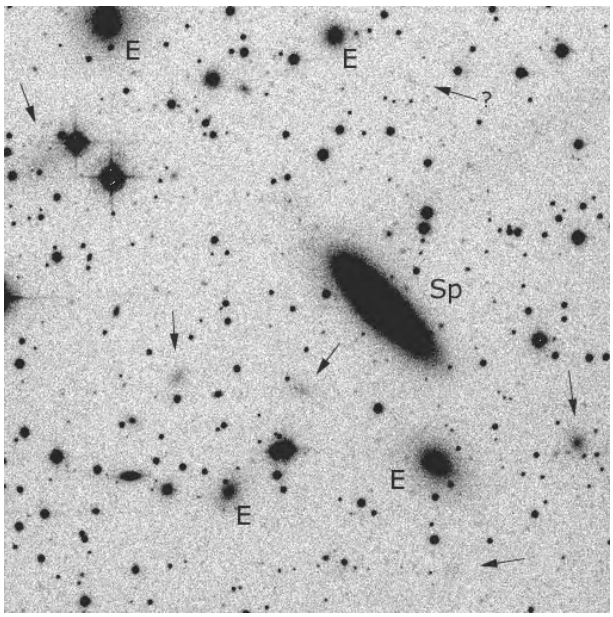

Figure 2. A close-up of a small region of the nearby Centaurus galaxy cluster. Five dSph galaxies within the cluster are denoted with arrows, and a sixth uncertain case is identified with an arrow and a question mark. The galaxies denoted with an 'E' are normal dwarf elliptical galaxies in the cluster and the elongated galaxy denoted 'Sp' is a spiral galaxy of the cluster viewed at a nearly edge-on orientation. Note how extremely diffuse and faint the dSph galaxies are relative to the other galaxies and to the brightness of the night sky itself. These features uniquely distinguish these dwarfs from normal ellipticals. Clusters such as Centaurus appear to be typical: dSph galaxies are the most common single type of galaxy known in the present-day Universe. This negative image was obtained at the Las Campanas Observatory of the Carnegie Institution of Washington and was provided courtesy of Kristin Chiboucas.

Dwarf spheroidal galaxies throughout the universe

Every galactic group or cluster that has been adequately studied has revealed large numbers of dSph galaxies. Most of these galaxies appear to be quite similar to the ones found in the Local Group, but some interesting variations are also found. For example, the nearby M81 group contains a few dSph galaxies that are considerably more extended and have even lower central surface brightnesses than the known local systems. Nearby galaxy clusters such as the VIRGO, FORNAX, CENTAURUS and COMA CLUSTERS contain hundreds to thousands of individual dSph galaxies (figure 2). Dwarfs with nuclei are particularly common in these environments, especially among the brighter galaxies. In most cases, the nuclei appear to contain stars that are distinctly different—possibly older or with different elemental abundances—from the majority of stars in the parent dSph galaxies.

Dwarf spheroidal galaxies appear to concentrate more towards the centers of galactic groups and clusters than any other type of galaxy, including spiral galaxies, large elliptical galaxies or the relatively dust-free S0 DISK GALAXIES. This is also observed in the Local Group where the vast majority of all dwarf companions nearest the Milky Way and the Andromeda Galaxy are dSph systems. Astronomers speculate that proximity of dwarfs to larger galaxies or the centers of large clusters helps remove gas from the smaller systems as a result of tidal forces or perhaps from interactions with isolated gas clouds also orbiting the larger systems. Either process can truncate star formation in the affected systems, allowing them to fade to very low surface brightnesses and ultimately resulting in the formation of dSph galaxies. Alternatively, dwarf galaxies near larger companions or near the dense centers of clusters may accelerate their star formation due

to interactions with their larger neighbors. Such galaxies would run out of gas and appear today to contain mostly middle-aged stars.

Two observations do suggest that dSph galaxies may interact tidally with their massive parents. First, none of these galaxies are found extremely close to a large galaxy, implying that tidal forces destroy dSph systems that venture too near to their parents. In the case of the Milky Way, the limiting distance appears to be about 150 000 light-years. Second, we actually see one example of the disruption occurring today. The Sagittarius dSph is unique among all known dSph galaxies in its enormous size and low density, both indicative of tidal disruption. This case really does appear to be one of a dSph galaxy in its final death throes. Models of its interaction with the Milky Way suggest that within about one billion years, Sagittarius will have dissolved away as a distinct galaxy, its stars scattered through the halo of our Galaxy.

Beyond about 100 million light years, dSph galaxies appear too small and too faint to be identified easily. However, their presence may still be inferred indirectly. Deep counts of galaxies have revealed a population of so-called faint blue galaxies located at such great distances that we are seeing the systems as they appeared many billions of years ago. Some of these could conceivably be dSph galaxies caught during one of their many strong episodes of star formation. Such events make the galaxies brighter and much bluer and consistent with the properties of at least some of the faint blue galaxies observed. Faint IRREGULAR GALAXIES appear to have global properties similar to dSph galaxies, but with the addition of young stars and a significant interstellar medium. Perhaps these represent modern-day examples of galaxies that have undergone evolution from a young, blue phase and are changing into typical dSph galaxies. Because dSph galaxies are so common and because most popular models of GALAXY FORMATION in the early universe suggest that small galaxies formed first, it may even be possible that dSph galaxies represent the basic unit of galaxy formation. If so, the dSph systems we see today may represent fossils of objects similar to the very first galaxies ever formed.

Dwingeloo Observatory

The Dwingeloo 25 m Telescope in Dwingeloo, The Netherlands, was inaugurated in 1956 and was for a short period of time the largest telescope in the world. For many years the Dwingeloo Telescope was the bread-and-butter instrument of the Dutch radioastronomy community. Its main operating frequency band around 1400 MHz allowed studies of the distribution of neutral hydrogen in our Galaxy and other nearby galaxies. The all-sky survey of the 21 cm line radiation of neutral hydrogen and the discovery of an unknown galaxy behind the plane of the Galaxy show that the DWT was a viable instrument until the end of its active life. The Dwingeloo Telescope was closed for observations in 1998 after 42 years of service.

The Dwingeloo Telescope was operated by the Netherlands Foundation for Research in Astronomy (NFRA), which is funded by the Netherlands Organization for Scientific Research (NWO).

Dyer Observatory

The Arthur J Dyer Observatory is the principal astronomical facility of Vanderbilt University. It is located about 16 km south of Nashville near Brentwood, Tennessee at an elevation of 345 m above sea level.

Built in 1953, the observatory houses a Seyfert 60 cm Cassegrain/reflector–corrector telescope and the DeWitt 30 cm Cassegrain, which is equipped for photoelectric photometry and long-focus photography. The telescopes are sometimes opened to the public.

Dynamical Reference Frame

The dynamical reference frame is a realization of a dynamical reference system which is based on the motions of the solar system (see SPACE AND TIME REFERENCES: CONCEPTS). It was the standard reference frame until it became possible to observe the positions of very distant radio sources with great accuracy.

The principle of the definition of a dynamical system of coordinates is to set the condition that the motion of celestial bodies can be represented by a solution of a system of differential equations of motion written in a fixed triad. This is verified by the fact that there is no need of any additional acceleration to account for the motion. To do away with a linear acceleration, one sets the center of the coordinates on the barycenter of the solar system, assuming that one takes into account the Coriolis acceleration due to the motion around the center of the Galaxy. Stopping the rotation of the axes is the major problem in building a dynamical frame, because there are no materialized invariant directions and one is reduced to describe as precisely as possible the motions of fiducial points accessible to observations.

Actually, there is a fixed reference plane defined by the solar system. It is the invariable, or Laplacian, plane. This is the plane normal to the axis of angular momentum and passing through the barycenter. This plane can be defined theoretically, but it is not observable. In addition, it is somewhat dependent upon the completeness of the bodies of the system included in its determination, and hence is unfit for practical use.

So, in practice the choice for the definition of the dynamical reference frame is the mean equatorial plane, the ecliptic plane, which is the mean orbital plane of the Earth without planetary perturbations, and one of the intersections of these planes, the equinox, which is the fiducial point.

The Earth, being our habitat and base for observations, becomes a natural basis for most reference frames. The equatorial plane is the most obvious and necessary reference plane, since the motions of all observatories are with respect to that plane. It can be determined from observational data either by determining the celestial pole or from diurnal motions of celestial sources. However, it is not fixed and moves due to gravitational forces by the Sun, Moon and planets on the bulge of the Earth and due to the dynamics of the many components of the interior, surface and exterior of the Earth. These motions are called precession, nutation and polar motion (see EARTH'S ROTATION).

Another natural plane of reference is the orbital plane of the Earth. This is subject to motions due to the perturbations of the planets and is changing continuously. The mean orbital plane of the Earth is called the ECLIPTIC. As long as a general theory by Newcomb was used to determine the ephemeris of the Earth, the ecliptic was well defined by the mean elements. With a numerical integration for the ephemeris of the Earth, the time period required to define the mean orbit is uncertain. The plane is also dependent on the ephemerides used to determine it.

The equinox is defined as the intersection of the eclipitic and the mean equator of the Earth. In determining this intersection from numerically integrated EPHEMERIDES, a distinction must be made. The equator can be taken as the instantaneous plane or as a uniformly moving plane. The historical determination was made based on the uniformly moving plane and that is the definition that has continued to be used. The difference between the two possible definitions of the equator is approximately a tenth of an arc second. For calendars, seasons, and holiday definitions the equinox is specified as the time when the Sun passes through either of the intersection points, i.e. when the apparent longitude of the Sun is zero or 180°.

Since both the equator and the ecliptic move due to solar, lunar and planetary gravitational forces on the shape of the Earth, and perturbations by the planets on the Earth's motion, the equinox moves with time. Therefore, the dynamical reference frame had to be specified for a specific epoch and observations and predictions were transformed to and from standard epochs to the chosen times of observations. The dynamical reference frame served as the fundamental reference frame of astronomy until 1998, when it was replaced by the International Celestial Reference System (ICRS), based on extragalactic radio sources, and thus fixed in space (see EXTRAGALACTIC REFERENCE FRAMES).

The new fiducial point does not have to revolve as the equinox did. The definition was arbitrary, but due to the inter-dependence of the definitions of time and coordinate systems, some optimum choices were possible.

The realization of the dynamical reference frame has been based on fundamental catalogs determined from observations of bright stars. These catalogs contained positions and proper motions based on some value of precession for the motion of the equinox. The fundamental catalogs were of two series, the US and German series (Eichhorn 1974). The Fundamental Catalogues series (FK3, FK4, and FK5) were used until 1998. The FK3 and FK4 were based on Newcomb's value of precession and a dynamical theory of motion of the solar system. FK5, introduced in 1984, was based on a revised value of precession and Jet Propulsion Laboratory Development Ephemeris DE 200. The introduction of the FK5 was also the occasion for the introduction of a new theory of nutation, new astronomical constants, and new definitions of timescales.

It was recognized that the FK5 defined a catalog equinox which was the origin of the right ascensions within the catalog. While this was attempted to be equivalent to the dynamical equinox defined by the solar system ephemerides, there was inevitably a difference between these two origins, called the catalog and dynamical equinoxes respectively, and this difference could be a function of time. The new ICRS defines a reference frame which is supposed to have its origin equivalent to the dynamical equinox of J2000.0, but again

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

there will inevitably be a difference between the equinox determined from the ephemerides and the ICRS origin. This difference will be dependent upon the ephemerides which will now be determined from observations reduced directly on the ICRS,

The motion of the equatorial plane is due to the torque of the Sun, Moon and planets on the dynamical figure of the Earth, it has been divided into long and short period terms. The smooth long-period motion of the mean pole of the equator about the pole of the ecliptic with a period of about 26 000 yr is lunisolar precession. The short-period motion, determined from the NUTATION theory, is made up of many terms with periods less than 18.6 yr, with a maximum amplitude of about 9″.0 (see EARTH'S ROTATION: THEORY).

The motion of the ecliptic is due to the gravitational action of the planets on the Earth's orbit and makes a contribution to precession known as planetary PRECESSION. If the equator were fixed, this motion would cause a precession of the equinox of about 12″ per century and a decrease in the obliquity of the ecliptic of about 47″ per century. The combination of lunisolar and planetary precession is called general precession. The causes of precession and nutation are the same, only the periods are different. There is some consideration being given now to eliminating the distinction.

At this time the officially adopted constant of general precession in longitude per Julian century at epoch J2000.0, $p = 5029.''0906$, is known to be incorrect by about $-0.''2957$ per century. The IAU 1980 Theory of Nutation is known to need improvement. The nutation theory for a rigid Earth has been improved and extended to smaller terms. However, the transformation from the rigid Earth model to the real non-rigid Earth model has not been determined to be consistent with observational data. Therefore, for accuracies of ± 1 mas the 1980 theory of nutation is satisfactory. For better accuracies, it is recommended that numerical values determined and distributed weekly by the International Earth Rotation Service (IERS) be used for both precession and nutation.

Dynamics

A galaxy is made up of stars in the same way that a crystal is made up of atoms, and the galaxy's large-scale properties reflect the forces that act between its component stars in the same way that the structure of a crystal reflects the nature of interatomic forces. Galaxies and crystals have strongly contrasting large-scale properties because a galaxy is held together by a force that has very different properties from a typical interatomic force.

For most purposes we may neglect the physical size of stars and consider them to be point particles that interact only through gravity. Gravity is a uniquely long-range force, so the net force on an individual star depends directly on the locations of every other star in the galaxy. By contrast, the net force on an atom in a crystal depends only on the location of up to a few dozen near neighbors.

Given that there are in excess of 10^{11} stars in a galaxy such as our own Milky Way, progress in STELLAR DYNAMICS would be slow if we had to know the locations of every star before we could calculate the motion of a single star. Fortunately, the problem can be simplified by arguing that the net force on a star does not depend sensitively on the precise locations of the billions of stars that are rather distant from it, so an excellent estimate of the contribution these stars make to the net force can be obtained by mentally smearing the mass of these stars into a smooth continuum of density. Mathematically, if in some region there are ν stars per unit volume, then we calculate the gravitational attraction from a smooth distribution of matter of density $\rho = \langle m \rangle \nu$ units of mass per unit volume, where $\langle m \rangle$ is the average mass of a star. The required gravitational attraction is easy to calculate if we first determine the gravitational potential that is generated by the density distribution ρ.

Replacing individual stars by a smoothed-out distribution of mass yields an indifferent estimate of the part of the force on a star that arises from the star's near neighbors. In particular, it completely neglects the fact that the star sometimes experiences short intense periods of acceleration when a neighboring star passes unusually close. This neglect of 'collisions' can be made good at a subsequent stage of the analysis, when collisional effects are added in to the 'collisionless dynamics' that are determined by approximating the system's mass distribution by a smooth one.

The longer a stellar system evolves, the more important collisional phenomena become. As a general rule, the time required for collisional effects to become important in a system of N stars is $\sim N/8 \ln N$ times the mean time it takes a star to cross the system. This time is substantially larger than the age of the universe in the case of a typical galaxy but significantly shorter than its age in the case of a typical STAR CLUSTER.

In this article we review the basic principles that govern the dynamics of galaxies and star clusters. More information on most topics will be found in the monograph [2], which will not be explicitly cited again.

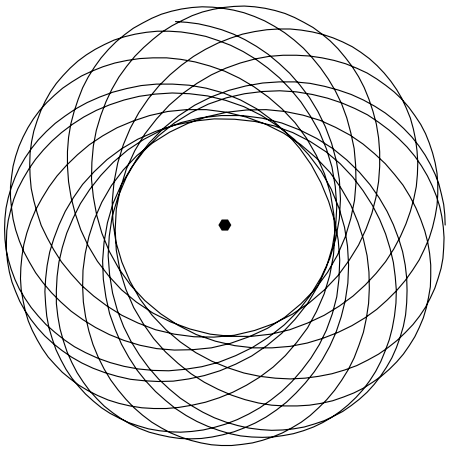

Figure 1. A typical orbit in a spherical potential.

Collisionless dynamics

A stellar system is usefully thought of as a collection of orbits in the smoothed-out potential of the system, each of which is populated by a certain number of stars. Consequently, a primary task of stellar dynamics is to understand what orbits can arise in a given gravitational potential.

The easiest case to consider is a spherical potential. Then every star moves in the plane perpendicular to the star's ANGULAR-MOMENTUM vector. Within this plane the star describes a rosette (figure 1). The orbit is best quantified by its angular momentum, $\boldsymbol{L}$, and its 'radial action' $J_{\rm r}$, which quantifies the vigor of the star's radial excursions: a circular orbit has zero radial action, $J_{\rm r} = 0$. The direction of the angular-momentum vector $\boldsymbol{L}$ defines the orbital plane, while the magnitude of the vector, L, controls the size and eccentricity of the orbit – if $J_{\rm r}/L$ is small, the orbit is nearly circular, and the orbit is physically small if L is small and large if L is large.

Few galaxies have spherical potentials, but many have potentials that are nearly axisymmetric. How do the orbits in a spherical potential change if we squash the potential along some axis, so that it remains axisymmetric about that axis? In a squashed potential, orbits are not confined to planes, but we can obtain a reasonably accurate picture of them by considering them to be confined to precessing planes. That is, the orbit is approximately confined to a plane that is inclined at some angle to the potential's symmetry axis, and slowly rotates about this axis. On the plane the orbit remains a rosette. The shape of this rosette is controlled by $J_{\rm r}$ and a number called I_3 in the same way that the shape of a rosette in a spherical potential was controlled by $J_{\rm r}$ and L. The inclination of the precessing orbital plane to the potential's symmetry axis is determined by the ratio I_3/L_z of I_3 to the star's angular-momentum about the potential's symmetry axis.

The potentials of many galaxies deviate significantly from axisymmetry, so let us ask what happens if we squash an axisymmetric potential along an axis perpendicular to

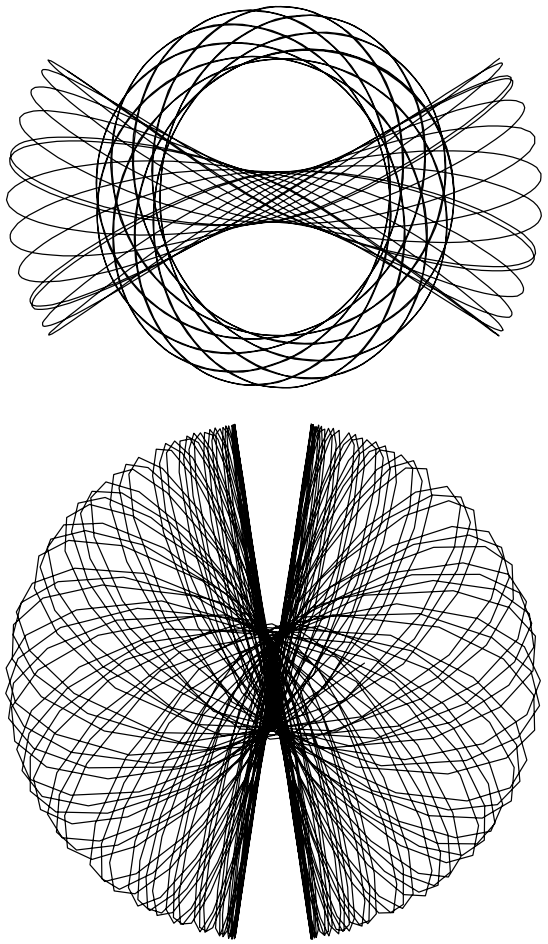

Figure 2. Three orbits in a triaxial potential. The contours of constant gravitational potential are elongated horizontally with axis ratio 0.9.

its symmetry axis. Figure 2 shows that the consequences of deforming a potential from axisymmetric to triaxial symmetry can be dramatic. While some orbits deform only slightly, others strongly amplify the deviation of the potential from axisymmetry.

When the potential of a galaxy is triaxial, it will usually tumble around one of its principal axes. The orbits shown in figure 2 are in a potential whose axes are fixed rather than tumbling. Figure 3 shows one important consequence of letting the potential tumble. The rate at which the potential tumbles defines a characteristic radius, the corotation radius, $r_{\rm CR}$, at which a star that moves around with the potential moves on a circular orbit. At radii much smaller than $r_{\rm CR}$, the rotation of the potential's figure is unimportant. At radii larger than about $r_{\rm CR}/10$ the orbits are profoundly modified by the figure rotation, and at radii close to $r_{\rm CR}$ a large fraction of the orbits are chaotic. Chaotic orbits such as that shown in figure 3 look rather ragged and have a propensity to change their character suddenly and irreversibly. It is likely that the steady accumulation of such changes drives the evolution of some galaxies, for example LENTICULAR GALAXIES.

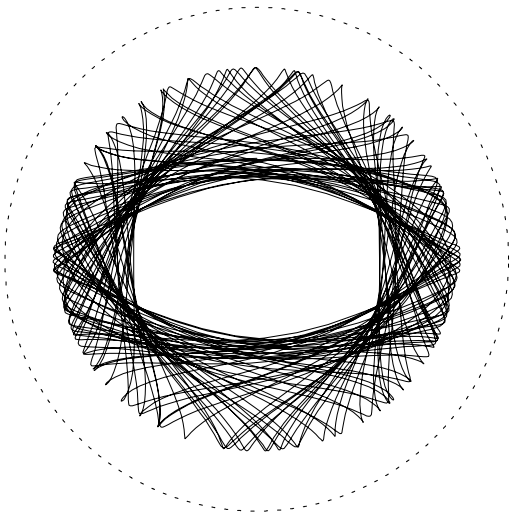

Figure 3. A chaotic orbit in a rotating barred potential. The dashed curve shows the potential's corotation radius.

Entropy and equilibrium

In stellar dynamics we seek statistical information in the sense that we would like to know the probability of the occurrence of any given configuration—in which given numbers of stars are on each orbit. In ordinary statistical physics the probability P that a given quantum state occurs can usually be obtained from the Gibbs distribution, $P \propto {\rm e}^{-\beta E}$, where $\beta = 1/kT$ is the inverse temperature and E is the energy of the state. Can this distribution be carried over into stellar dynamics?

The answer to this question is 'no'. In fact, the concept of thermodynamic equilibrium ultimately fails for any self-gravitating system, including every stellar system. The reason for this failure is very interesting and can be understood by considering a self-gravitating system of mass M and characteristic radius R. The energy of the system is then of order $U = -GM^2/2R$, and, by the 'virial theorem', the mean-square random velocity of the system's constituent particles (atoms or stars), $\langle v^2 \rangle$, is of order $\langle v^2 \rangle = GM/R$. As in ordinary kinetic theory, we identify the system's temperature as

$$T = \frac{\langle m \rangle \langle v^2 \rangle}{3k} = \frac{GM\langle m \rangle}{3kR} = -\frac{2U}{3Nk}$$

where k is Boltzmann's constant and N is the number of particles (atoms or stars) in the system. Now imagine putting the system into thermal contact with a slightly cooler reservoir of heat. Heat will flow out of the system into the reservoir. By conservation of energy, the system's internal energy U will become more negative and, by the equation above, T will increase. This behavior is quite the reverse of what we observe in every-day life: when heat

flows out of a coffee cup, it cools down rather than heats up.

We can show that this anomalous behavior of self-gravitating systems drives them away from thermal equilibrium by considering such a system to be made up of two parts: the core and the envelope. If the system is very centrally concentrated, the core is orders of magnitude denser than the envelope and the core's equilibrium is very little affected by the presence of the envelope, so the relation between internal energy and temperature that we derived above can be applied to the core alone. The envelope is confined by a mixture of the 'external' gravitational field of the core and its own self-gravity, so its temperature and internal energy will be connected by a relation that lies somewhere between that derived above for a perfectly self-gravitating system and that appropriate for a classical gas, in which U is positive and $T = \frac{2}{3}U/Nk$. In general we may write $T = \alpha U/Nk$, where $-\frac{2}{3} \leq \alpha \leq \frac{2}{3}$ depending on the degree to which the envelope is self-gravitating.

If initially the core and the envelope are in thermal equilibrium, they must have a common temperature T. Consider a thermal fluctuation that transfers a small quantity of heat, δU, from core to envelope. This transfer causes the temperature of the core to rise by $\delta T_{\rm core} = 2\,\delta U/3Nk$ (because the energy of the core changes by $-\delta U$), while the temperature of the envelope will rise by $\delta T_{\rm env} = \alpha\,\delta U/Nk$. Since the envelope must be to some extent self-gravitating, $\alpha < \frac{2}{3}$ and $\delta T_{\rm core} > \delta T_{\rm env}$. Consequently, after the fluctuation, the core is hotter than the envelope, and the temperature gradient between core and envelope starts to drive a steady flow of heat from core to envelope. This flow increases the temperature difference between core and envelope, and a 'gravithermal catastrophe' ensues in which $T_{\rm core}$ rises inexorably.

The sequence of events that we have just described prevents any classical self-gravitating system, whether it be a star or a galaxy, from achieving thermal equilibrium. None the less, the concept of thermal equilibrium is invaluable in understanding the structure of a star, because in a star there is usually a well-defined temperature at any given radius since individual atoms or photons do not stray far between collisions. In a stellar system, by contrast, stars move at constant energy through wide ranges in radius, and the distribution of stellar velocities at a given radius is not characteristic of any particular temperature.

Although the analogy between the structure of a star and a stellar system is imperfect, the theory of STELLAR EVOLUTION does provide valuable insights into the dynamics of stellar systems. Stars start out in life relatively homogeneous. Gradually the gravithermal catastrophe causes the core to contract and heat up, and the envelope to expand and cool, with the observational consequence that the star becomes a RED GIANT. All stellar systems are at some point on this trek towards every greater central condensation. It is a journey without end because one can show that, no matter what its current configuration, the entropy of a stellar system can be increased by a transfer of energy from the dense interior to the more rarefied exterior.

Dynamics of star clusters

What varies from system to system is the rate at which such transfers are proceeding and the physical processes responsible for them. The systems that evolve in closest analogy with a star are star clusters. In these systems, which contain from a few hundred to perhaps a hundred thousand stars, collisional processes are important in two contexts. First, they effect a transfer of heat from the contracting core to the expanding envelope. Second, they enable energy to be released in the core in much the same way that in a stellar core nuclear reactions release energy. The mechanism of this energy release is as follows. When a single star approaches a BINARY STAR closely, it exchanges energy with the binary and will often form a triple star in which all three stars are bound. Subsequently, two of the three stars will move towards one another, releasing energy which is used to eject the third star at speed. Hence, the net result of the formation of the triple star is the replacement of a relatively slow-moving free star by a much faster one. Over time, this faster star will tend to lose energy to stars that it encounters as it moves through the cluster. Binary stars, being more massive than most single stars, tend to sink to the core. Moreover, the rate at which any given binary star will suffer close encounters with single stars is highest in the dense environment of the core. So most of the energy that is liberated by binary–star encounters heats the core rather than the envelope. It follows that a star cluster resembles a star in that its core is heated and its envelope transmits a flux of thermal energy outwards.

A star cluster's core responds to heating by expanding, and thus reducing the rate at which binary–star encounters heat it. Consequently, oscillations in the density of the core can arise, in which expansion and decreased heating is followed by contraction and increased heating, and then the cycle repeats [6].

Dynamics of elliptical galaxies

ELLIPTICAL GALAXIES differ from GLOBULAR CLUSTERS principally in scale: whereas a globular cluster contains of order 10^5 stars, a massive elliptical galaxy contains in excess of 10^{12} stars. In addition to being much more massive than globular clusters, elliptical galaxies are physically larger too. In fact, a massive elliptical galaxy may have several thousand globular clusters bound to it, with ample space for them to move through the galaxy just like stars. The vast number of stars in an elliptical galaxy, and the huge volume within which they are distributed combine to render collisional effects entirely unimportant. So whereas collisional effects are constantly moving a globular cluster down a well-defined evolutionary path, an elliptical galaxy spends most of its time stuck in a particular configuration. What physical processes got it into the configuration in which it is now frozen?

The answer to this question is not entirely clear, but undoubtedly two important processes are mergers and cannibalism.

In the absence of collisional effects, an individual star can change the energy of its orbit only when the overall galactic gravitational potential is changing. This fact implies that the evolution of a collisionless galaxy is concentrated into brief episodes of violent change: revolution rather than evolution. During one of these episodes of change, rapid change in the overall gravitational potential causes individual stars to gain and lose energy fairly rapidly. This vigorous exchange of energy between stars in turn drives the rapid evolution of the overall potential.

An episode of rapid change in the gravitational potential can be initiated by a close encounter with another galaxy. If the intruding galaxy comes close enough and moves slowly enough, the two galaxies become a binary galaxy within which the gravitational potential is constantly changing as the galaxies swing around each other while moving alternately closer together and further apart.

As the gravitational potential changes, some stars gain energy and others lose it, but overall more energy is picked up than lost by stars. The net gain of energy by stars is mirrored by a net loss of energy from the relative orbit of the two galaxies. Hence the galaxies spiral together and eventually merge (see GALAXIES: INTERACTIONS AND MERGERS).

The time required for the galaxies to merge completely depends on their relative initial masses. If the two galaxies are initially of comparable size, merging is complete by the time the galaxies have orbited around each other two or three times. If one galaxy is much less massive than the other, more orbits are required for merging—in order of magnitude, the number of orbits required is equal to the mass of the bigger galaxy divided by the mass of the smaller. When this ratio is large, the larger galaxy seems to eat the smaller, and one speaks of 'cannibalism'.

The configuration of the galaxy that emerges from a merging event depends significantly on the mass ratio of the merger. If the mass ratio is close to unity, the merger product tends to be triaxial in shape and at most slowly rotating. Larger mass ratios are more likely to produce axisymmetry and significantly rotating merger products [7].

Nuclear black holes

It is likely that all substantial galaxies contain massive central BLACK HOLES—we know for certain that our own Milky Way has a black hole of mass $\sim 2 \times 10^6 M_\odot$, and that our nearest giant neighbor, the ANDROMEDA GALAXY M31, has an even more massive nuclear black hole. The presence of nuclear black holes in galaxies that merge has important consequences for the dynamics of the merger remnant. First, and most conspicuously, the irregular and time-varying gravitational potential of the merging galaxies feeds a significant fraction of any gas in the system onto the black holes, which are then liable to become ultraluminous as they accrete some of this abundant gas supply. In the final stage of the merger, when the nuclei of the two galaxies have spiralled very close together, the black holes can have a significant impact on the distribution of stars in their vicinity. Indeed, the merger leads to the formation of a binary black hole that initially moves through a centrally concentrated sea of background stars. One by one the stars gain energy from the binary black hole and move out to larger radii. Over time the density of the stellar sea ceases to be centrally concentrated. In consequence of losing energy to background stars, the orbit of the binary black hole shrinks and shortens in period until it begins to be relativistic in the sense that its period is not extremely long compared with the time light requires to cross it. When this stage is reached, the radiation of GRAVITATIONAL WAVES by the orbit becomes the dominant mechanism of energy loss. As the orbit shortens further in period, the intensity of the radiated gravitational waves and the rate of orbital decay rapidly accelerate. The merger of the holes must then ensue, surely one of the most awesome events the universe is ever called upon to witness.

Over a long time-scale, the final, merged, black hole can profoundly modify the enveloping galaxy [5, 8]. The galactic merger will frequently have left the latter triaxial. Its triaxiality is sustained by 'box' orbits like that shown in the top panel of figure 2. A star on such an orbit is liable to pass very close to the galactic center, where the black hole resides. If on some passage it comes very close to the black hole, it will be deflected through a large angle and emerge on a very different orbit, like that shown in the bottom panel of figure 2. Clearly, when a sufficient number of stars have been transferred in this way from elongated orbits to fat orbits, the galaxy will become less elongated overall. Moreover, this is liable to be a run-away process: transfers of stars from elongated to fat orbits make the overall galactic potential less elongated, and this reduction in the elongation of the potential reduces the elongation of the orbits of other stars, that have passed nowhere near the black hole.

The details of these processes—the ejection of stars from galactic centers by binary black holes and the probably catastrophic erasure of triaxiality following scattering of high-energy stars by a merged black hole—have not been fully worked out [9], but it is likely they account for the observed fact that lower-luminosity elliptical galaxies have cuspy and probably axisymmetric centers, while more luminous systems have more nearly homogeneous and probably triaxial centers [1].

Dynamics of disk galaxies

Many, perhaps essentially all, stars form in centrifugally supported disks of gas. Consequently, the dynamics of disks of gas and stars is of vital importance for galactic dynamics (see also DISK GALAXIES).

Imagine a disk of stars in which every star is on a circular orbit. This is an equilibrium configuration, but it turns out to be a violently unstable one that will quickly break up into rings of enhanced density separated by

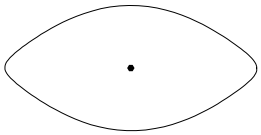

Figure 4. In a suitably rotating frame of reference the rosette orbit of figure 1 closes. The filled point marks the centre of the potential.

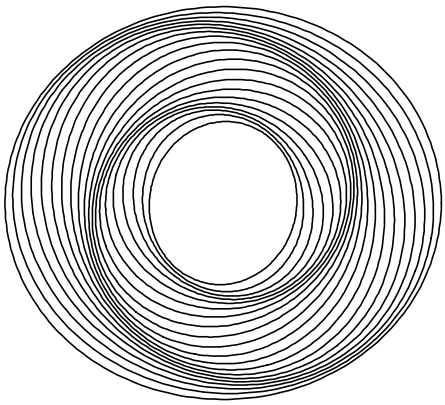

Figure 5. When elliptical orbits are arranged so that the orientation of each major axis changes smoothly with radius, spirals of enhanced density are generated.

density depressions. To avoid rapid fragmentation, the stars of a disk must have random velocities in addition to rotating around the galactic center, and the higher the surface density of the disk, the larger the random velocities of stars need to be if fragmentation is to be avoided.

Since the stars of a stable disk have random velocities, they have to be on non-circular orbits, so they must be on rosette-like orbits such as the one shown in figure 1. If we view such an orbit from a frame of reference that rotates at the right frequency, ω_p, the orbit looks closed as in figure 4. If we populate such an orbit with many stars uniformly distributed in phase around the orbit, we have an elliptical hoop of stars, whose long axis rotates steadily at the angular velocity ω_p—we say that the hoop 'precesses' with frequency ω_p. Notice that the precession frequency ω_p is entirely distinct from the frequency Ω at which individual stars circulate around the hoop—Ω is generally much greater than ω_p. Figure 5 shows what happens if we superimpose many hoops of stars, each with a slightly different radius and initial orientation of its long axis. Spiral arms of enhanced density appear.

Figure 5 describes the essence of how the arms of SPIRAL GALAXIES are constructed. What makes the dynamics of these systems extremely complex is the fact that, in an axisymmetric potential, the precession frequency ω_p varies with the radius of the hoop. In fact, the precession frequency of the innermost orbits in the figure will generally be higher than that of the outermost orbits shown, with the consequence that the spiral pattern will gradually wind up into an ever tighter spiral.

In reality, the spiral arms will contribute a significant non-axisymmetric component to the gravitational potential, and we need to ask how this component affects the precession frequencies of individual hoops. The non-axisymmetric component of the potential applies torques to each ring, and these torques can either increase or decrease the hoop's precession frequency. The idea behind the normal mode theory of spiral structure is to find a configuration of the hoops—essentially a rule, $\phi_0(a)$, for the initial orientation of a hoop's major axis as a function of semimajor axis length, a—such that the torques speed up the slowest hoops and slow down the fastest ones, so that all hoops rotate at the same rate, and the spiral pattern that they form rotates like a rigid body. In these circumstances, ω_p is called the 'pattern speed' of the spiral arms.

Determining the function $\phi_0(a)$ is a mathematically challenging problem and the theory of spiral structure has not often been approached by this direct route. The usual approach is to start from the insight that a self-gravitating disk of stars is a medium that is capable of supporting waves, in the same way that the surface of a pond is. If we disturb the stars at some radius, r_0, we will change the way they contribute to the overall surface density near r_0, and thus we will change the gravitational potential in which other, previously undisturbed stars move. Hence, the motion of these other stars will be disturbed, and they will in turn disturb yet other stars. In fact, our disturbance will spread from radius r_0 like a ripple over a pond.

When waves move in a confined region, such as a teacup or a piano wire, resonant frequencies arise. Waves with these frequencies can travel from a source, and, after possibly multiple reflections from the boundaries, return to the point of origin with the same phase regardless of the number of times that they have been reflected. Because the waves always return with the same phase, they interfere constructively and achieve a significant net amplitude. The resonant frequencies of a simple system such as a piano wire can be exactly determined by finding the frequencies at which waves that are reflected numbers of times interfere constructively. The resonant frequencies of a teacup cannot be found exactly in this way, but good approximations to them can be found thus.

The 'density-wave' theory of spiral structure interprets spiral structure as generated by resonant spiral waves and yields approximate values for the possible pattern speeds and shapes of spiral arms. A significant complication of the theory arises because a typical galactic disk does not have well-defined boundaries like those of a teacup or a piano wire. Boundaries of a sort emerge once one chooses a pattern speed ω_p for the desired spiral pattern. These boundaries are defined by radii at which a star moving on a nearly circular orbit in the undisturbed axisymmetric potential of the galaxy can resonate with a disturbance of frequency ω_p. The inner boundary is the radius of the 'inner Lindblad resonance' (ILR). At this radius the star rotates faster than ω_p, so it regularly overtakes the spiral wave pattern, and the frequency at which it experiences the wave coincides with the frequency, ω_r, of its

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

natural oscillations in radius. The outer boundary is the edge of an annulus in which spiral disturbances cannot propagate. This annulus is centered on the 'corotation resonance', which is the radius at which a star could move on a circular orbit at frequency $\omega_{\rm p}$. Spiral structure arises when leading spiral waves propagate out towards corotation and are reflected and amplified into trailing waves at the edge of the corotation annulus. The amplified trailing waves then propagate in towards the ILR, where they are refracted into leading waves that move back out to corotation, completing the cycle.

A piano wire is not fundamentally changed by the passage along it of waves. A stellar disk, by contrast, is significantly modified by spiral waves. Such waves increase the random velocities of stars that are in resonance with them. This increase in random velocities is a reflection of the tendency of trailing spiral arms to transport angular momentum out from the ILR and thus to enable stars at the ILR to move inwards. In fact, spiral arms achieve for stellar disks something very similar to what mergers achieve for elliptical galaxies: an increase in the central concentration and entropy of the system. Since the ability of a disk to sustain spiral arms decreases as the random velocities of stars increase, spiral structure will eventually die away in a purely stellar disk. Spiral galaxies such as our own have sustained strong spiral structure for a Hubble time because they have star-formation rates that are fairly constant in time. Young stars have small random velocities and so enhance the disk's ability to support spiral arms.

If one releases from an axisymmetric equilibrium a disk in which stars have very small random velocities, the disk very quickly becomes strongly non-axisymmetric. The non-axisymmetry is not primarily due to spiral structure, however, but to a tumbling bar. The dynamics of a tumbling bar is analogous to that of the spiral arms shown in figure 5: large numbers of orbits are elongated with major axes that rotate at a common frequency, $\omega_{\rm p}$. A bar differs from a spiral disturbance in that (i) individual orbits tend to be much more strongly elongated in a bar, and (ii) in a bar the major axes are all aligned, irrespective of the radius of the orbit. A large proportion of spiral galaxies, including the Milky Way, have bars at their centers. In a strong bar, a significant fraction of all stars have a chance to pass arbitrarily close to the galactic nucleus, where a massive black hole is expected to lurk. In close analogy to what happens in a triaxial elliptical galaxy, deflection of stars by the gravitational potential of the black hole can lead to the dissolution of the bar [10].

Dynamics of the Milky Way

We live far out in the disk of a BARRED SPIRAL GALAXY, and from this vantage point can study many of the physical processes described above [1]. Figure 6 is a plot of the random velocities of groups of solar-neighborhood stars versus the age τ of the stellar group: the open circles show the group's rms velocity $\sigma_{\rm r}$ in the direction to the Galactic center, and the full points

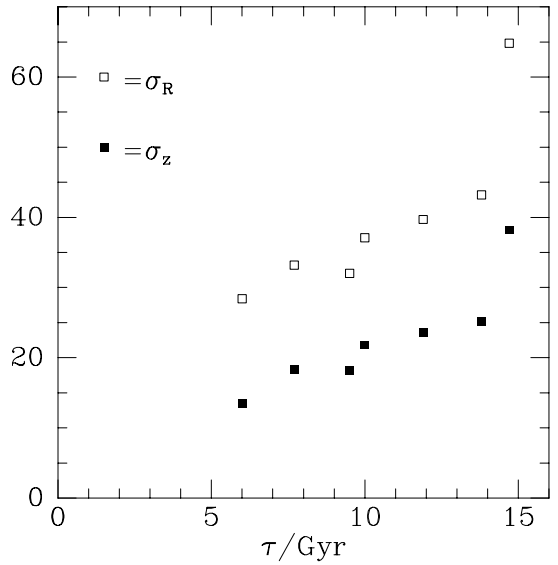

Figure 6. Velocity dispersion versus age for stars in the solar neighborhood. Data from [11].

show the rms velocity σ_z perpendicular to the Galactic plane. The unambiguous increase in rms velocity with age demonstrates that, although collisional processes are unimportant for the Milky Way, the solar neighborhood is evolving dynamically. We believe that spiral waves drive the increase in σ_r. These waves cannot be directly responsible for the increase in σ_z, however. Clouds of molecular gas with masses in the region of $10^5 M_\odot$ are thought to be responsible for this increase: the gravitational fields of these objects deflect stars that have picked up significant random motion within the plane into the direction perpendicular to the plane, so that they henceforth make significant excursions above and below the plane.

Figure 6 shows that the random velocities of stars are highly anisotropic in the sense that the random velocity perpendicular to the plane is not much larger than a half of that in the radial direction. The velocity dispersion in the tangential direction, σ_ϕ, lies between these two extremes, and there is an interesting connection between the ratio σ_ϕ/σ_r and the way the speed of a circular orbit varies with galactocentric radius.

Figure 7 shows the difference between the Sun's velocity in the direction of Galactic rotation and the mean velocity in this direction of various stellar groups as a function of the random velocity, S^2, of each stellar group. We see that the Sun is moving faster around the Galactic centre than any stellar group, and the amount by which a stellar group lags the rotation of the Sun tends to increase with the group's random velocity. The physical origin of this observation is that the hotter a stellar disk is, the more slowly it needs to spin to be in centrifugal equilibrium in a given gravitational potential; a hot stellar disk has significant pressure support. Each stellar group forms an

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

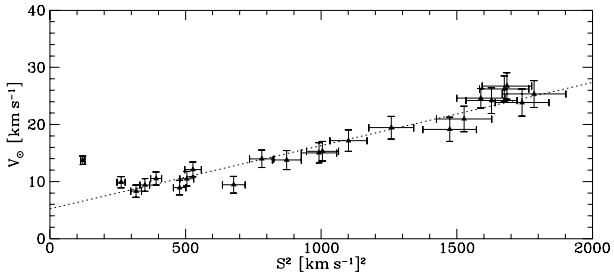

Figure 7. The velocity of the Sun in the direction of Galactic rotation relative to the mean velocity of different stellar groups. S^2 is the mean-square random velocity of each group. Data from [3].

independent disk, which spins at its own rate. The Sun happens to belong to one of the coolest, fastest-spinning disks, and within that disk happens just now to be one of the fastest-circulating stars (see also SUN AS A STAR).

When we look at stars that lie 1 or 2 kpc from the Sun, we see that the mean velocity of the stars at a given place varies from point to point around the Galaxy. This effect mainly reflects the fact that the Galactic disk is a swirling accretion disk, a sort of vortex, in which stars stream around the Galactic center at a speed that varies with radius. In fact, historically observations of this effect were a primary source of data from which the Galactic potential's run of circular speed with radius was inferred. Unfortunately, the data are not easy to interpret, in part because, as we have just seen, the speed with which a population of stars circulates depends on the population's velocity dispersion, and in part because, as we shall now see, the pattern of stellar flow within the Galaxy is in reality more complex than simple circular motion.

If we identify a group of stars, we can measure its 'velocity-dispersion tensor', which is the 3×3 matrix whose elements σ_{ij}^2 are the averages $\langle v_i v_j \rangle$ of products of velocity components. The diagonal elements of this matrix are just the squares of the velocity dispersions that we have just been discussing: $\sigma_{rr}^2 = (\sigma_r)^2$. If the Galaxy were axisymmetric, the off-diagonal elements would vanish. In fact the component $\sigma_{r\phi}^2$ is significantly non-zero for every group of solar-neighborhood stars. Responsibility for this observational result probably lies with two agents. For groups of stars that have small random velocities and therefore stay near the Sun, the non-zero values of $\sigma_{r\phi}^2$ are probably caused by spiral structure. In the case of a group of stars with large ($\sim$50 km s^{-1}) velocities relative to the Sun, the non-zero value of $\sigma_{r\phi}^2$ is probably caused by the bar at the Galactic center. The length of this bar is somewhat uncertain, but probably lies near 3 kpc, rather less than half the Sun's distance from the Galactic center, R_0. Stars with larger velocities relative to the Sun travel on their orbits to sufficiently small Galactocentric radii that they are profoundly influenced by the non-axisymmetric potential of the bar.

Figure 8 is a plot against radius r of the mass $M(r)$ contained within a sphere of radius r around the Galactic center. This plot was made by studying the kinematics of gas clouds and stars that lie near the Galactic centre and then applying simple dynamical theory. For radii greater than about a parsec, $M(r)$ decreases with r, but, at smaller r, M levels out at a value of order $2 \times 10^6 M_\odot$. The natural interpretation of this result is that a black hole of this mass sits at the Galactic center and that stars make a comparable contribution to M only at radii larger than about a parsec.

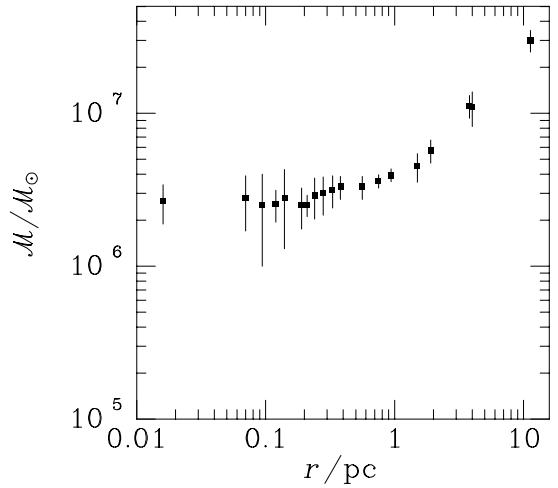

Figure 8. The mass $M(r)$ contained in a sphere of radius r around the Galactic center. Data from [4].

Dynamo Theory

Dynamo theory is that branch of MAGNETOHYDRODYNAMICS which is concerned with the self-excitation of magnetic fields in any large rotating mass of conducting fluid in motion (usually turbulent). Self-exciting dynamo action is believed to account for the very existence of magnetic fields in astrophysical systems, whether at the planetary, stellar, or galactic scale (see GEODYNAMO, DYNAMOS: SOLAR AND STELLAR).

The process of self-excitation occurs when fluid motion across a magnetic field generates the current distribution which is itself the source of the 'given' magnetic field. This principle is most simply illustrated by the example of the 'homopolar' disk dynamo sketched in figure 1: a conducting disk rotates about its axis with angular velocity Ω, and a current path between its rim and its axle is provided by the wire twisted as shown in a loop around the axle. Suppose that a current $I(t)$ flows in the loop, the current circuit being closed through the axle of the disk and the disk itself. This current generates a magnetic flux Φ across the disk, and, provided that the conductivity of the disk is not too high, this flux is given by $\Phi = MI$ where M is the mutual inductance between the loop and the rim of the disk. Rotation of the disk induces an electromotive force $E = \Omega\Phi/2\pi$ which drives the current I; the equation for $I(t)$ is then

$$L\frac{\mathrm{d}I}{\mathrm{d}t} + RI = \mathcal{E} = \frac{M\Omega I}{2\pi} \tag{1}$$

where L and R are the self-inductance and resistance of the complete current circuit. The device is evidently unstable to the growth of I (and so of Φ) from an infinitesimal level if

$$\Omega > 2\pi R/M. \tag{2}$$

In this circumstance, the current grows exponentially, as does the retarding torque associated with the Lorentz force distribution in the disk. Ultimately, the disk angular velocity slows down to the critical level $\Omega_0 = 2\pi R/M$ at which the driving torque G just balances this retarding torque, and the current can remain steady. In this equilibrium, the power supplied $\Omega_0 G$ is equal to the rate of Joule dissipation RI^2 (assuming that frictional torques are negligible).

This simple system exhibits the dual property of any self-exciting dynamo: the current in the system generates the magnetic field (without the assistance of any 'external' source), and motion of a conductor across the field generates the current that maintains it. Note the following properties of the system which re-emerge in the more general fluid context, and which appear to be more or less universal concomitants of dynamo action: (1) the system exhibits 'differential rotation' in that the disk rotates, while the wire is at rest (the gradient of angular velocity is here concentrated at the two sliding contacts); (2) in order for the system to act as a dynamo, the wire must be twisted in the same sense as the sense of angular

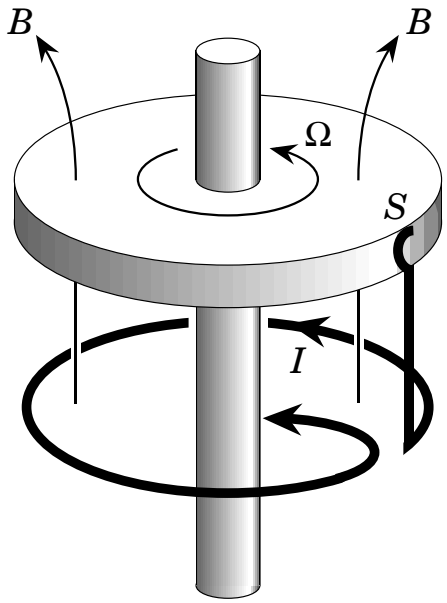

Figure 1. The self-exciting homopolar disk dynamo. Note that the wire is twisted in the same sense as that of the rotation Ω.

velocity of the disk, i.e. there is a definite 'handedness' in the system, a property which, in the fluid context, is generally encountered as a non-zero 'helicity' of the fluid flow (see MAGNETIC HELICITY).

There is a further intriguing property of this simple system, however, which indicates the dangers of too simplistic an argument when dealing with a medium of very high conductivity. If the conductivity of the disk were infinite, then we know that the flux of magnetic field across its rim must remain constant by Alfvén's theorem (magnetohydrodynamics) a result clearly incompatible with exponential growth of flux. What happens in this situation is that an additional current is induced round the rim of the disk which is just such as to maintain the constancy of the trapped flux. This perhaps indicates that, when we move to the much more difficult fluid context, great care will be needed in analysing the high-conductivity limit, which is of particular relevance in stellar and galactic contexts.

The stretch–twist–fold dynamo

Consider an initially circular magnetic flux tube of small cross-section embedded in a highly conducting incompressible fluid. We may easily imagine a doubling of the intensity of the magnetic field by a movement analogous to the doubling of an elastic band: first stretch the tube to double the radius, then twist and fold it in the manner indicated in figure 2. This process evidently doubles the net magnetic flux around the (now composite) tube; if the process is repeated over and over again, then a successive doubling, analogous to exponential growth, occurs. This is what is conventionally known as the stretch–twist–fold dynamo. It relies on the idea that, in

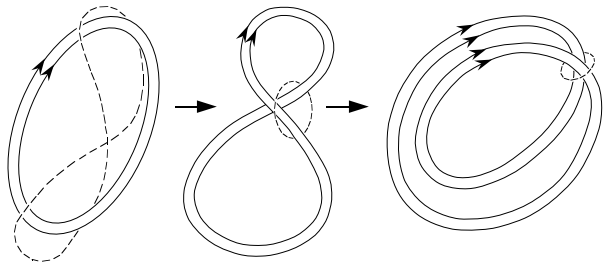

Figure 2. The stretch–twist–fold action applied to a magnetic flux tube; the reciprocal action on a linked material circuit is indicated by the dashed curve.

a perfectly conducting fluid, 'magnetic lines are frozen in the fluid', so that, in a highly conducting fluid, a similar behavior is to be expected. Although the idea is physically plausible, it is difficult to establish the existence of this type of dynamo by rigorous mathematical argument. One difficulty is that the stretch–twist–fold action necessarily introduces a twist within the tube itself (as can be easily seen by applying the twist–fold action to a ribbon in the form of a circle).

If we trace backwards in time the effect of the above distortion on a Lagrangian material circuit round the doubled flux tube (the dashed curve in figure 2), then it is easy to see that this curve must have started as a twisted curve embracing the circular tube twice. Hence the stretch–twist–fold action has the reverse effect on this Lagrangian circuit. An alternative magnetic flux tube, starting in the position of the dashed curve, would thus be diminished by the same distortion. Things are evidently not as simple as they might appear at first sight.

Formal definition of dynamo action

We start from the magnetic induction equation

$$\frac{\partial \boldsymbol{B}}{\partial t} = \boldsymbol{\nabla} \wedge (\boldsymbol{u} \wedge \boldsymbol{B}) + \eta \nabla^2 \boldsymbol{B} \tag{3}$$

where $\boldsymbol{B}$ is the magnetic field, $\boldsymbol{u}$ the velocity field and η the magnetic diffusivity of the fluid. $\boldsymbol{B}$ also satisfies the supplementary condition $\mathrm{div}\boldsymbol{B} = 0$. If the velocity field $\boldsymbol{u}$ is steady (i.e. $\boldsymbol{u} = \boldsymbol{u}(\boldsymbol{x})$), then we may look for solutions of equation (3) in the form of 'eigenmodes',

$$\boldsymbol{B}(\boldsymbol{x}, t) = \mathrm{Re}\, \hat{\boldsymbol{B}}(\boldsymbol{x}) e^{pt}. \tag{4}$$

The amplitude function $\hat{\boldsymbol{B}}(\boldsymbol{x})$ then satisfies the equation

$$p\hat{\boldsymbol{B}} = \boldsymbol{\nabla} \wedge (\boldsymbol{u} \wedge \hat{\boldsymbol{B}}) + \eta\, \nabla^2 \hat{\boldsymbol{B}} \tag{5}$$

which, when coupled with appropriate boundary conditions, defines an eigenvalue problem for the exponent p, the field $\hat{\boldsymbol{B}}$ being then the corresponding eigenfunction. p may in principle be real or complex: $p = p_r + \mathrm{i}\, p_i$. If $p_r > 0$ then the corresponding solution of equation (3) exhibits dynamo action: there is evidently a systematic increase in intensity of the magnetic field with growth rate p_r. If $p_i = 0$, the dynamo action is a simple exponential growth, while if p_i is non-zero, then the field at any point oscillates with exponentially growing amplitude.

Solution of the above eigenvalue problem evidently depends on the parameter η which appears in equation (5). Let us suppose that the velocity field is characterized by a length scale l and a velocity scale u_0, so that the magnetic Reynolds number $R_m = u_0 l/\eta$ may be defined. In astrophysical contexts, we are usually concerned with the situation in which R_m is very large, and particular attention must therefore focus on the behavior of p and $\hat{\boldsymbol{B}}$ as R_m tends to infinity. This consideration has led to a formal distinction between 'slow' and 'fast' dynamos. Roughly speaking, the dynamo is fast if p_r is proportional to u_0/l (i.e. independent of η) in the limit $R_m \to \infty$. If, on the other hand, $p_r l/u_0 \to 0$ as $R_m \to \infty$, then the dynamo is slow.

The stretch–twist–fold dynamo considered above is perhaps the best candidate for characterization as a fast dynamo; in a single period of the stretch–twist–fold cycle, it exhibits a doubling of flux, but at the cost of introducing a certain degree of 'fine structure' in the field. Actually, this appears to be a property of any fast dynamo. Equation (5) can be easily analyzed in the formal limit $\eta = 0$. It has been shown that a fast dynamo can exist only if the corresponding field $\hat{\boldsymbol{B}}$ exhibits fine structure on scales of order $R_m^{-1/2}$. In the limit $\eta = 0$, such fields become non-differentiable.

Attempts have been made to circumvent this difficulty by widening the class of solutions of equation (3) to which the term 'fast dynamo' may be ascribed. The reader is referred to the book by Childress and Gilbert (1995) for an account of investigations, based largely on Lagrangian and associated mapping techniques, in this area.

We may note that the homopolar disk dynamo is, for the reasons indicated in the introduction, definitely a slow dynamo, i.e. its growth rate tends to zero as the magnetic Reynolds number, based on disk angular velocity and conductivity, tends to infinity.

Cowling's theorem

In planetary and stellar contexts, it was natural that early investigations should focus on axisymmetric systems. In 1934, COWLING established that axisymmetric dynamo action is impossible, a result which, for many years, falsely led people to assume that all dynamo action was impossible (see Cowling 1957). It is important, nevertheless, to understand the basic nature of Cowling's argument, if only to see how the associated difficulties may be circumvented. Consider an axisymmetric magnetic field generated by currents contained entirely within a sphere (figure 3). The 'toroidal' currents within the sphere (i.e. those in the ϕ direction in a system of cylindrical polar coordinates r, ϕ, z) act as the source of the 'poloidal' part of the magnetic field $\boldsymbol{B}_P$ (i.e. that part with components in the r and z direction). This poloidal field, being associated

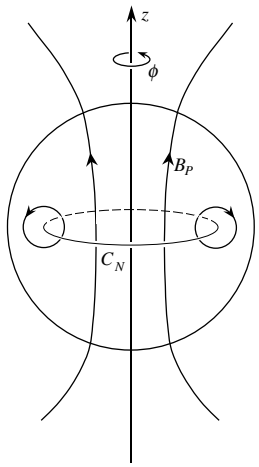

Figure 3. Cowling's theorem: induction cannot maintain current in the neighborhood of the circle C_N if the flow and field are axisymmetric.

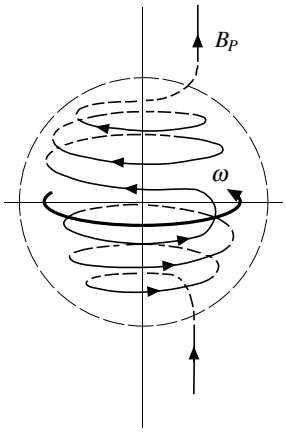

Figure 4. Generation of toroidal field by differential rotation with a variation of angular velocity along each field line.

with a compact source, has at most a dipole structure at a great distance from the sphere. The Earth's magnetic field of course provides an excellent example of this phenomenon. The lines of force of this dipole field must have at least one 'O-type' neutral point, and this neutral point must lie inside the sphere of conducting fluid. There is an associated circle C_N of neutral points around the axis of symmetry. The toroidal current distribution can be driven only by fluid motion across the poloidal magnetic field and this effect is absent on C_N where $\boldsymbol{B}_P = 0$. Consequently any toroidal current on C_N must necessarily decay through normal Ohmic diffusion associated with finite conductivity ($\eta > 0$). Thus, steady maintenance of an axisymmetric magnetic field in a finite volume of conducting fluid is impossible.

This argument of course needs to be formalized, but this can be done, and indeed many extensions of Cowling's theorem have been proved. Essentially, it is well established that, if a steady magnetic field is to be maintained in a finite region containing fluid of finite conductivity, then the field, and the motions that support it, must be non-axisymmetric. This theorem accounts for much of the mathematical difficulty of the subject and for the long period that elapsed following the proof of the theorem before explicit examples of dynamo action in a homogeneous fluid were discovered.

The generation of toroidal field by differential rotation

One mechanism, which is essentially axisymmetric in character, is nevertheless of great importance in the dynamo context. Let us suppose for the moment that a poloidal magnetic field is maintained by some (as yet unspecified) mechanism. Consider the action of a purely toroidal velocity field on this magnetic field. If the angular velocity is constant along every field line, then these field lines are simply rotated around the axis of symmetry with the corresponding angular velocity (the law of 'isorotation'). If, on the other hand, there is any gradient of angular velocity along a field line, then that field line will tend to be drawn out in the toroidal direction, an effect that will be limited only by diffusion effects (figure 4). If the magnetic Reynolds number is large, then the field line may be 'cranked' round the axis many times before this diffusion effect intervenes. Detailed analysis based on equation (3) indicates that the toroidal field that is generated increases until it is $O(R_m)$ times the initial poloidal field. At this stage, in general, Ohmic diffusion establishes a steady state.

This is evidently a powerful mechanism whereby toroidal fields may be generated from a pre-existing poloidal field. The great difficulty is to explain how it is that the poloidal field can be generated in the first place. For this purpose, it is absolutely necessary to consider non-axisymmetric effects. The greatest impetus to this subject has undoubtedly come from the assumption at the outset that the fluid motion is fully turbulent, an assumption that is of course utterly reasonable in stellar and galactic contexts. Even in the case of planetary interiors, although the fluid motions are extremely weak (of the order of fractions of a millimeter per second) it seems highly likely that these motions, while not necessarily fully turbulent, will nevertheless have a significant non-axisymmetric ingredient.

Mean field electrodynamics

The idea behind mean field electrodynamics is that we are generally concerned in dynamo theory with the development of a 'large-scale' magnetic field, i.e. with a field that is coherent over the global scale of the planet or star or galaxy under consideration. The turbulence, or other random motion, which plays a part in the dynamo process in general has a very much smaller characteristic length scale. There is therefore a significant

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

scale separation which can be exploited in the construction of a theory for the large-scale field.

Let us first suppose that, in some region of fluid which contains many constituent eddies of the turbulence, the large-scale ingredient of the field may be treated as nearly uniform. The velocity $\boldsymbol{u}$ distorts the mean field $\boldsymbol{B}_0$, generating a fluctuating component $\boldsymbol{b}$. If we average equation (3) over the scale l of the turbulent fluctuations, then we obtain an equation for the mean field $\boldsymbol{B}_0$, namely

$$\frac{\partial \boldsymbol{B}_0}{\partial t} = \boldsymbol{\nabla} \wedge \boldsymbol{\mathcal{E}} + \eta \nabla^2 \boldsymbol{B}_0. \tag{6}$$

Here, a term appears resulting from the interaction between two fluctuating fields, namely

$$\boldsymbol{\mathcal{E}} = \langle \boldsymbol{u} \wedge \boldsymbol{b} \rangle. \tag{7}$$

This is the 'mean electromotive force' associated with the fluid motion. We have assumed that the average of $\boldsymbol{u}$ itself and similarly the average of $\boldsymbol{b}$ are zero. Nevertheless, any correlation between $\boldsymbol{u}$ and $\boldsymbol{b}$ will result in a non-zero value for $\boldsymbol{\mathcal{E}}$.

In order to proceed further, it is necessary to obtain an equation for the fluctuating field $\boldsymbol{b}$. This is obtained by simply subtracting equation (6) from equation (3) to give

$$\frac{\partial \boldsymbol{b}}{\partial t} = \boldsymbol{\nabla} \wedge (\boldsymbol{u} \wedge \boldsymbol{B}_0) + \boldsymbol{\nabla} \wedge (\boldsymbol{u} \wedge \boldsymbol{b} - \langle \boldsymbol{u} \wedge \boldsymbol{b} \rangle) + \eta \nabla^2 \boldsymbol{b}. \tag{8}$$

This equation evidently establishes a linear relationship between $\boldsymbol{b}$ and $\boldsymbol{B}_0$, and hence, via equation (7), between $\boldsymbol{\mathcal{E}}$ and $\boldsymbol{B}_0$. Since $\boldsymbol{B}_0$ is nearly uniform, this linear relationship may be expressed in the form

$$\mathcal{E}_i = \alpha_{ij} B_{0j} + \beta_{ijk} \frac{\partial B_{0j}}{\partial x_k} + \cdots \tag{9}$$

where the coefficients α_{ij}, β_{ijk}, and so on, do not depend on the field $\boldsymbol{B}_0$ but are determined (in principle) solely by the statistical properties of the turbulence $\boldsymbol{u}$ and the magnetic diffusivity η.

The implications of equation (9) are most easily understood if it is assumed that the background turbulence is isotropic (i.e. there is no 'preferred direction'), so that the tensor coefficients α_{ij}, β_{ijk}, etc. are also isotropic. In this case, we may write

$$\alpha_{ij} = \alpha \delta_{ij} \qquad \beta_{ijk} = \beta \epsilon_{ijk} \tag{10}$$

and the corresponding expression for $\boldsymbol{\mathcal{E}}$ is then given by

$$\mathcal{E} = \alpha \boldsymbol{B}_0 - \beta \, \boldsymbol{\nabla} \wedge \boldsymbol{B}_0 + \ldots. \tag{11}$$

The corresponding form of equation (6) then becomes

$$\frac{\partial \boldsymbol{B}_0}{\partial t} = \alpha \nabla \wedge \boldsymbol{B}_0 + (\eta + \beta) \nabla^2 \boldsymbol{B}_0. \tag{12}$$

There is here a very important effect to notice, an effect first described in a seminal paper by Steenbeck, Krause and Rädler in 1966 (see Krause and Rädler 1980). Since $\boldsymbol{\mathcal{E}}$ is a polar vector, whereas the magnetic field $\boldsymbol{B}_0$ is an axial vector, the coefficient α in equation (11) must be a pseudo-scalar, i.e. a quantity which changes sign under change from a right-handed to a left-handed frame of reference. By contrast, the coefficient β is a pure scalar, independent of frame of reference. It is evident from equation (12) that β simply serves to augment the molecular diffusivity of the fluid, i.e. we can describe β as a turbulent diffusivity. By contrast, the coefficient α is associated with a term of novel structure in the induction equation; moreover, for a field of very large length scale, it is this term that dominates the right-hand side. The effect, appropriately described as the 'α effect', is crucial to an understanding of dynamo theory.

Dynamo instability associated with the α effect

To understand this effect in the simplest possible way, it is sufficient to consider a field structure $\boldsymbol{B}_0(x)$ satisfying the Beltrami condition

$$\boldsymbol{\nabla} \wedge \boldsymbol{B}_0 = K \boldsymbol{B}_0 \tag{13}$$

where K is a constant (positive or negative). The ABC field

$$\boldsymbol{B}_0 = \begin{pmatrix} B \cos Ky + C \sin Kz \\ C \cos Kz + A \sin Kx \\ A \cos Kx + B \sin Ky \end{pmatrix} \tag{14}$$

provides an example of such a field, as may be easily verified, but there are many others (see FORCE-FREE MAGNETIC FIELDS). Since, for such a field, $\nabla^2 \boldsymbol{B}_0 = -K^2 \boldsymbol{B}_0$, equation (11) simplifies to the form

$$\frac{\partial \boldsymbol{B}_0}{\partial t} = \alpha K \boldsymbol{B}_0 - (\eta + \beta) K^2 \boldsymbol{B}_0. \tag{15}$$

Hence $\boldsymbol{B}_0$ is proportional to e^{pt}, where

$$p = \alpha K - (\eta + \beta) K^2 \tag{16}$$

and dynamo instability occurs if $p > 0$, a condition that is always satisfied if $\alpha K > 0$ and $|K|$ is sufficiently small, i.e. provided that the scale $L = 2\pi/|K|$ is sufficiently large. This condition is certainly consistent with the initial assumption that the scale of the mean field be large compared with the scale of the turbulence. Thus, in the presence of a non-zero α effect, the medium is always unstable to the growth of magnetic field perturbations on a sufficiently large length scale.

This effect is one of the most remarkable discoveries of the last 50 years. It indicates how order, represented by the large-scale magnetic field, may emerge from chaos, represented by the small-scale turbulence in the medium.

Evaluation of α

It remains, however, to develop a convincing theory for the determination of the all-important parameter α in terms of the statistical properties of the background turbulence. We have already noted that α is a pseudo-scalar; it can therefore be non-zero only if the statistical properties of the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

turbulence have a crucial property of 'lack of reflectional symmetry'. The simplest measure of a lack of reflectional symmetry in a turbulent flow is its mean helicity

$$\mathcal{H} = \langle \boldsymbol{u} \cdot \operatorname{curl} \boldsymbol{u} \rangle \tag{17}$$

the mean of the scalar product of the velocity field and the vorticity field curl $\boldsymbol{u}$. This is analogous to magnetic helicity. The helicity is related to the topological structure of the vorticity field, which is conserved in the classical situation in which vortex lines are frozen in the fluid. It may be expected that, if this mean helicity is non-zero, then α will in general be non-zero also.

It is indeed possible to calculate α explicitly in any circumstances in which the fluctuating ingredient of the magnetic field $\boldsymbol{b}$ is weak compared with the mean field. In such circumstances, it is found that

$$\alpha = -\frac{1}{3}\eta \int\int \frac{k^2 H(k,\omega)}{\omega^2 + \eta^2 k^4}\, \mathrm{d}k\, \mathrm{d}\omega \tag{18}$$

where $H(k,\omega)$ is the helicity spectrum of the turbulence, satisfying the defining relationship

$$\langle \boldsymbol{u} \cdot \operatorname{curl} \boldsymbol{u} \rangle = \int\int H(k,\omega)\, \mathrm{d}k\, \mathrm{d}\omega. \tag{19}$$

Thus, α is linearly related to the helicity spectrum of the turbulence. In these integral expressions, k is a wavenumber magnitude and ω a frequency. Note that, in the limit as $\eta \to 0$, the expression (18) for α depends critically on the behavior of the helicity spectrum for small values of frequency ω. Unfortunately, it is in this double limit ($\eta \to 0$, $\omega \to 0$) that the theory yielding the expression (18) is at its least convincing.

Physical mechanism of the dynamo process

The dynamo process associated with the α effect may be represented schematically as in figure 5. Background turbulence with helicity provides an α effect, the dynamo parameter being related to the helicity through equation (18) (or some higher-order version of this equation). This α effect generates an electromotive force (EMF) $\boldsymbol{\mathcal{E}}$ parallel to $\boldsymbol{B}_0$ (through the equation $\boldsymbol{\mathcal{E}} = \alpha \boldsymbol{B}_0 + \cdots$) and this EMF drives a mean current $\boldsymbol{J}_0$ parallel to $\boldsymbol{B}_0$. The resulting mean field has non-zero magnetic helicity, and so the tubes of force of $\boldsymbol{B}_0$ are generally linked. The prototype linkage is shown in figure 5; the current driven round each tube provides (via Ampère's theorem) the mean magnetic field in the other tube.

Three vital conditions ensure the success of this process:

- the turbulence must have non-zero helicity;
- the fluid must have finite non-zero magnetic diffusivity;
- the fluid domain must be large enough to provide space for the growth of the large-scale magnetic field.

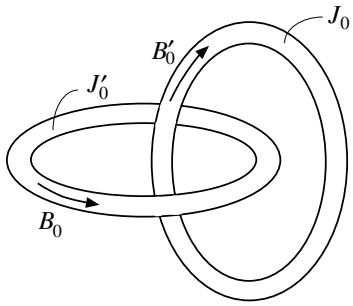

Figure 5. The dynamo cycle associated with the α effect. The current J_0 is associated with the field B_0, and the current J_0' with B_0'

The α–ω dynamo mechanism

As we have seen above, the α effect in isolation can easily give rise to dynamo instability; we have shown this to be true in a medium of infinite extent; however, a similar mechanism certainly occurs in any sufficiently large spherical domain of conducting fluid in turbulent motion.

If the fluid in such a domain is rotating with mean angular velocity Ω, then turbulent convection within the domain in general leads to a state of 'differential rotation' in which the inner regions rotate more rapidly than the outer regions. As we have seen, differential rotation provides a powerful mechanism whereby toroidal field can be generated from poloidal field. The α effect provides the vital complementary mechanism whereby poloidal field can be regenerated from toroidal field. If the turbulence is isotropic, then the same α effect contributes to the regeneration of toroidal field from poloidal field, but the differential rotation effect is generally much more powerful.

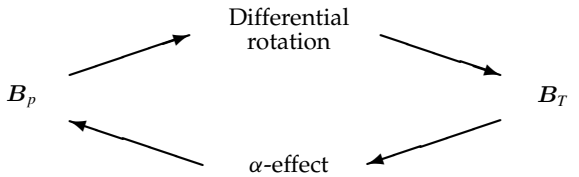

Figure 6. Field regeneration through the α–ω dynamo cycle.

These considerations lead to consideration of dynamos of 'α–ω type' as indicated schematically in figure 6. Here, the dynamo cycle consists simply of two stages: generation of toroidal from poloidal field by differential rotation and regeneration of poloidal from toroidal field by the α effect. Many numerical investigations of the resulting mean field dynamo equations have demonstrated the efficiency of this type of self-exciting dynamo.

Back-reaction of Lorentz forces

The above outline description of the process of dynamo action is purely 'kinematic', in that it assumes that the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

velocity field, or in the case of turbulent flow the statistics of the velocity field, is prescribed independently of the magnetic field. In circumstances in which dynamo action occurs, the amplitude of the magnetic field grows exponentially in time, and so therefore does the Lorentz force, which is quadratically related to the magnetic field. This Lorentz force reacts back upon the fluid motion so that the velocity field itself depends on the magnetic field that it generates. The dynamo process then enters a nonlinear regime, whose complexities can generally be unravelled only through numerical simulation of the full magnetohydrodynamic equations.

It is also necessary to specify the nature of the forces that sustain the motion, and the associated dynamo, against dissipative effects which now include viscosity as well as Joule dissipation. This is equivalent to specifying the source of energy of the fluid motion; this source may be of thermal origin (as in the solar context); in the context of the terrestrial dynamo driven by fluid motion in the liquid core the source of energy is more likely to be associated with segregation of light material during the process of solidification of the inner core, a process that provides buoyancy forces of 'compositional' rather than thermal origin. Either way, the need to include consideration of the buoyancy field adds significantly to both the physical and the mathematical complexity of the problem.

The study of fully non-linear dynamos, taking account of the diverse possible sources of energy, is an area of very vigorous current research, and great advances are to be expected over the next 10–20 yr.

Dynamos: Solar and Stellar

The direct observation of magnetic fields on the surface of the Sun (see SOLAR MAGNETIC FIELD), as well as on the surface of other stars (see MAGNETIC FIELDS IN STARS), directly raises the question of the origins of these magnetic fields. The simplest hypothesis is that these magnetic fields are simply the remnants of magnetic fields carried in by the accreting gas during the formation phase of such stars, but a number of observational facts make this explanation untenable for stars such as the Sun: the observed fields are globally relatively weak, but locally very strong, much stronger than would be expected of decaying remnant fields dating back to the formation of the Sun, and the global magnetic fields are observed to vary systematically in a roughly periodic fashion (in the Sun's case, this periodicity is roughly 22 yr (see SOLAR ACTIVITY INDICES)). These observations instead argue for the presence of a process which is capable of re-generating the magnetic field of a star such as the Sun on a time scale of roughly 11 yr; this is the process referred to in the following as a (stellar magnetic) dynamo (see DYNAMO THEORY).

At the outset, it is important to distinguish between the large-scale (i.e. stellar-scale) and small-scale behavior of stellar magnetic fields, which can be drastically different. In the Sun's case—the only case for which we have detailed, spatially resolved observations—it is the large-scale fields that show the cyclic, activity-related temporal variations; these large-scale fields are weak (1–10 G), in the sense that their energy density is substantially smaller than that associated with either the thermal energy content of the Sun's surface layers or the kinetic energy density of these same layers. In contrast, the small-scale solar fields, i.e. the fields on spatial scales comparable with the convective surface motions, can be strong (up to 3000 G), in the sense that their energy density can be of the order of, or even larger than, the kinetic energy density of the surface layers and is of the order of the plasma internal energy density of these layers. These locally strong fields show a much more complex temporal behavior, much of which is not directly tied to the cyclic behavior of the large-scale fields (see SOLAR PHOTOSPHERE: INTRANETWORK AND TURBULENT MAGNETIC FIELDS). This temporal distinction between the behavior of large-scale and small-scale magnetic fields is a crucial argument supporting the current view that the origins of the large- and small-scale fields may be unrelated.

Mean field solar dynamos

As discussed elsewhere (see DYNAMO THEORY), the challenge for solar and stellar dynamo theory was originally to construct a physically plausible mechanism for re-generating both the poloidal and the toroidal components of the Sun's relatively weak large-scale magnetic field. (It is important to note that the importance of small-scale solar magnetic fields was not appreciated at the time, primarily because direct measurements of these fields were not possible.)

Since the 1940s, it has been recognized that differential rotation in the interior or surface layers of the Sun could generate toroidal magnetic flux from a pre-existing poloidal magnetic component; the missing link was a similar physical process re-generating the poloidal component from the toroidal one. This link was found in the mid-1950s by E N Parker. He showed that motions of conducting PLASMA associated with MAGNETIC BUOYANCY and convection, which carry (toroidal) magnetic flux radially outward, will be subjected to Coriolis forces if the star rotates; this rotation-dependent force twists the rising and falling plasma bubbles precisely the right way so that the trapped toroidal fields produce a poloidal component. With the addition of a phenomenological model for an enhanced eddy diffusivity, Parker was able to construct a solar magnetic dynamo model which reproduced all of the classical features of large-scale solar magnetic activity: the 22 yr periodic variation of the toroidal and poloidal fields, the butterfly diagram of magnetic field emergence, showing flux emergence closer and closer to the solar equator as one half of a magnetic cycle proceeds, and the Hale polarity law of local flux emergence, which states that the leading polarity of emerging bipolar fields always lies closer to the solar equator.

In Parker's original model, the differential rotation needed to re-generate the large-scale toroidal field was assumed to be the result of radial differential rotation, i.e. Parker assumed that the Sun rotates more quickly in its interior than in its surface layers; at that time, this differential rotation was unobserved, and therefore unconstrained. Later workers such as H Babcock produced variants of Parker's model which took advantage of the observed (surface) DIFFERENTIAL ROTATION in latitude and were able to produce dynamo models which were similar in successfully describing the large-scale features of the Sun's magnetic field. Additional work was carried out in studying the evolution of the emerged magnetic fields. Thus, R Leighton showed that the asymmetry of magnetic flux emergence associated with Hale's polarity law, when combined with a simple random walk model of flux diffusion on the solar surface (consistent with Parker's eddy diffusion model), naturally leads to a migration of surface magnetic fields to the solar poles in which the following polarity dominates at the poles. In this picture, the observed small-scale magnetic fields were viewed as detritus of the decaying large-scale fields and as the seeds for the next generation of large-scale poloidal fields.

By the mid-1970s, magnetic dynamo models of the type first described by E N Parker were well understood from both the phenomenological and the formal, mathematical perspectives: the Potsdam group of dynamo theorists, as well as the work of K Moffatt and collaborators in the UK, and Parker and collaborators in the US, had firmly established the foundations of mean field theory in MAGNETOHYDRODYNAMICS. However, two advances in the 1970s and early 1980s led to a questioning of mean field theory. First, high spatial

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

resolution observations of surface solar magnetic fields by J Stenflo, J Harvey and others began to raise serious questions about the applicability of mean field theory to the Sun—observations indicated that while the large-scale fields were indeed weak, this was not true of the small-scale fields. In mean field theory, it is assumed that the small-scale fields are weak, in the sense that they are not strong enough to react back on the fluid motions; in contrast, direct measurements showed that these small-scale fields were, in contradiction, strong enough to affect fluid motions. These back reactions were capable, in principle, of destroying the underpinnings of mean field theory; for example, it is by no means clear that the large eddy diffusion required by mean field theory can exist if the small-scale fields significantly affect small-scale fluid motions. In addition, computing advances in the early 1980s had reached the stage that it became possible to solve the fully nonlinear magnetohydrodynamic equations for a convective spherical shell, albeit for very limited spatial resolution, and such simulations by P Gilman and collaborators showed that the large-scale behavior of the numerical solutions did not correspond very closely to either mean field theory or observations of the Sun's magnetic cycle.

Recent work

Much of the recent work on solar and stellar dynamos has grown out of the concerns raised about mean field dynamo models, as well as new observational and computational tools. For example, the realization that small-scale magnetic fields may play an important role in the solar dynamo led to the exploration of new classes of dynamo models for the large-scale magnetic fields by M Schüssler and collaborators. These models take as their starting point the notion that the magnetic field in the solar interior is in a highly filamentary, flux tube, form (see SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES). The exploration of the consequences of such a dynamo model, including studies of the dynamics of rising magnetic flux tubes in the convection zone (see SOLAR INTERIOR: CONVECTION ZONE), is a very active area of research today.

The advent of solar seismology (HELIOSEISMOLOGY) (see HELIOSEISMIC OBSERVATIONS) allows us to focus on another aspect of solar dynamo theory, namely the interior rotation rate of the Sun, and the precise location of the dynamo. Concerns about the precise location of the solar dynamo were raised as early as the late 1970s, when it was suggested by N O Weiss, E Spiegel, R Rosner and others that the Sun's toroidal fields might be plausibly produced in the subadiabatic undershoot layer lying beneath the solar convection zone, where these fields could be stably stored. This idea has received much recent attention because helioseismological observations have indicated that there is a layer of substantial differential rotation (the 'tachycline') lying at the base of the solar convection zone (see SOLAR INTERIOR: ROTATION), i.e. precisely in the region where the earlier models had placed the toroidal field production region. This area of research is also currently very active.

In the early 1970s, S Vainshtein and Y Zel'dovich demonstrated the existence of a new class of dynamos—the so-called 'fast dynamos'—whose properties did not depend on the molecular diffusivity in the limit of very large magnetic Reynolds numbers. This type of dynamo has the property that rotation is not essential to its existence, and it is thought that the maximal spatial scale of the magnetic fields produced by such a dynamo is comparable with the maximal spatial scale of the driving turbulent motions (see MAGNETOHYDRODYNAMICS: MAGNETOCONVECTION). At the time, the connection between such dynamos and specific astrophysical magnetic fields was still unclear. Recent advances in computing power now allow direct numerical simulations of the fully nonlinear magnetohydrodynamic equations that have far greater spatial dynamic range than what could be done in the 1980s; as a result, it is now feasible to carry out detailed numerical experiments of fast dynamos. Using flows which are variously driven by specified external random 'stirring' or by imposed thermal fluxes (thus driving thermal convective flows), F Cattaneo, D Hughes and collaborators have been able to show that magnetic fields which are locally in equipartition are readily produced by such flows. The volume filling factor of the strong fields depends on the precise mixing characteristics of the flows themselves; and the morphology of the surface flows and surface magnetic flux in the convectively driven calculations uncannily resembles recent observations of solar magnetic fields and surface convective motions obtained from the MDI instrument on board the SOHO spacecraft. These calculations—which show that the magnetic field in chaotic flows has a highly fractal spatial structure—also call into question the existence of magnetic 'flux tubes' as discrete, relatively long-lived entities. This area of research is also extremely active today.

Stellar dynamo problems

Quite aside from the precise mechanism by which stellar magnetic fields are produced, we also do not have a good understanding of a number of additional aspects of stellar magnetic activity.

Magnetic activity at the end of the main sequence

Surveys of the nearby stars have shown that stellar activity as measured by the x-ray to bolometric luminosity ratio does not change significantly as one proceeds down the main sequence to low-mass stars (see SOLAR–STELLAR CONNECTION and STELLAR ACTIVITY). However, surveys of very low mass stars (e.g. stars that may be, or are, classified as brown dwarfs) suggest that some of them may well be inactive (see EXTRASOLAR PLANETARY COMPANIONS AND BROWN DWARFS). Although the lack of evidence is not evidence for absence, it is known that some sort of transition from the above-described convection-driven activity should occur at sufficiently low mass: for example, we know that the observed activity of the giant gaseous planets in our solar

Copyright © Nature Publishing Group 2001

system is not solar like at all, but is instead the result of the interaction of planetary magnetospheres with the solar wind (see PLANETARY MAGNETOSPHERES); for gaseous planets, magnetic field 'stirring' at the planetary surfaces by surface flows is a negligible source for their activity, while such stirring by photospheric motions is precisely how we believe stellar chromospheres and coronae are energized. Thus, observations of both the Sun and stars, as well as planets in our solar system, allow us to conclude that rotating, self-gravitating objects (stars and giant gaseous planets) produce magnetic fields in their interior via a dynamo process, that these objects are all 'active' and that the underlying basic physics that drives the activity in these two cases is may be drastically different in its origins. However, exactly how this transition between solar-like behavior and planetary behavior occurs is not yet understood.

A related issue revolves around the nature of convection, and the nature of the interior dynamo, as one proceeds to lower- and lower-mass objects. Classical stellar structure theory predicts that stars become fully convective at spectral type ∼dM5 (see HERTZSPRUNG–RUSSELL DIAGRAM and STELLAR INTERIORS), and, based on recent ideas that the base of the convection zone should play a particularly important role in magnetic dynamos, one would expect to see a transition in activity behavior at ∼dM5—yet no such transition has been observed. How can we understand this? It may be possible that, in the presence of even relatively modest interior magnetic fields, low-mass stars never become fully convective, i.e. that magnetic fields stabilize the deep interior in the mean, but a definitive answer remains elusive at the time of writing.

Magnetic A stars

Observations of late spectral type B–A main sequence stars have established the existence of a subclass of such stars that show the presence of extremely strong surface magnetic fields, with reports of extreme examples of fields with strength in excess of 30 kG. Temporal variations of the polarized Zeeman signal from these stars show only variations related to stellar rotation; secular variations that might be interpreted as cycle-related changes have not been observed from these stars. The implication is either that these magnetic fields are primordial in origin or that the dynamo process responsible for these fields has a substantially longer characteristic time scale than stellar dynamos associated with the surface convection zone of late-type main sequence stars.

Spot stars

Observations of main sequence stars of spectral type K and M have shown that the more active stars of this type can display substantial bolometric luminosity variations that have been attributed to the presence of large 'star spots' on their surface (see RED DWARF STARS). While solar sunspots typically occupy areas of order 10^{-6}–10^{-5} of the visible solar disk, these starspots can occupy 30% or more of the visible surface of the active star. While there has been a revolution in the study of such stellar surface features with the introduction of Doppler imaging, little is understood theoretically about the formation of such spots. For example, the type of local fast dynamo process discussed earlier, which gives good account of the small-scale magnetic flux production on the solar surface, cannot be trivially extended to explain these enormous magnetic features.

Dyson, Sir Frank Watson (1868–1939)

Astronomer, born in Measham, Leicestershire, England, Astronomer Royal for Scotland and afterwards for England. Directed (with SIR ARTHUR STANLEY EDDINGTON) the 1919 eclipse expedition which confirmed the deflection of starlight by the Sun's gravity, as predicted by Einstein's general theory of relativity. Directed measurements of terrestrial magnetism, latitude and time at the Royal Observatory and initiated the radio broadcast of time.

Eötvös, Baron Lóránd [Roland] von (1848–1919)

Hungarian physicist, born in Pest (now part of Budapest), became professor of experimental physics there. Worked on wide range of physical problems including gravitation, and invented the *Eötvös balance*, a torsion balance. With it, he tested (in what became known as the *Eötvös experiment*) the equivalence principle that gravitational mass and inertial mass are equivalent; he found that they were identical to less than five parts in a billion. The equivalence principle was originally due to GALILEO and given prominence by EINSTEIN in the theory of general relativity.

Eagle Nebula (IC 4703)

An emission nebula in the constellation Serpens, position RA $18^{h}\ 18.8^{m}$, dec. $-13^{\circ}\ 47'$. It measures about $30'$ across and surrounds the open cluster M16 (NGC 6611); it is often mistakenly given the cluster's designation. Its shape is vaguely reminiscent of an eagle in flight, though some dark nebulosity near its center bears a closer resemblance to an eagle. The nebula is the site of star formation, especially in huge twisting columns of dark nebulosity nicknamed 'elephant trunks' or 'the pillars of creation'.

Earth: Space-based Observations

In the wake of World War II, the US Naval Research Laboratory began experimenting with German-designed V-2 rockets as well as smaller, lighter launch vehicles called 'sounding rockets'. In order to monitor which way the rockets were pointing during their flights, scientists began putting aircraft gun cameras on them. During one of these flights, on 7 March 1947, the first space-based picture of Earth was taken at an altitude of 100 miles over New Mexico. In 1950, upon developing the film after another of these flights, scientist Otto Berg discovered a series of pictures of a huge tropical storm over Brownsville, Texas. He pieced the pictures together into a mosaic of the region enveloped by the storm, thus demonstrating the potential for space-based cameras to help us monitor our changing world (see also ROCKETS IN ASTRONOMY).

Interest quickly grew among the international community of Earth scientists in using sounding rockets to study the Earth's upper atmosphere. In 1952, the International Council of Scientific Unions proposed declaring 1957 the 'International Geophysical Year' (IGY) to satisfy a growing desire among scientists to expand the study of our home planet to include the whole Earth system and its surroundings. In 1954, the IGY committee challenged participating countries to launch a satellite as part of the IGY activities. On 29 July 1955, President Dwight Eisenhower announced that the United States would launch about six Earth satellites as a contribution to the IGY. On the following day, Premier Nikita Kruschev said the Soviet Union would also launch satellites during the IGY, and the race was on between the superpowers.

In October 1957, the Soviet Union successfully launched Sputnik I—a 22-inch spherical satellite weighing 175 pounds—into a low-Earth orbit. In January 1958, the United States successfully launched Explorer I, followed by the launch of Vanguard I two months after that. But the Russians' success and the United States' initial failures spread a sense of crisis in the latter country. The Americans declared space exploration a national priority, and in 1958 President Eisenhower asked his Science Advisory Committee to write a policy on space. Later that year Congress signed the act creating the National Aeronautics and Space Administration (NASA). Since then, NASA has played an international leadership role in developing and deploying satellite technologies for Earth observation.

A space-based perspective

The Soviet–American race to demonstrate technological superiority yielded a fortunate byproduct for Earth scientists—a newfound perspective from which to study our world. In 1959 the Russians, again followed closely by the Americans, launched the first humans into space. Looking back, the cosmonauts and astronauts saw the Earth as a tiny oasis of life—unique, as far as we know—adrift in a seemingly lifeless sea. Against the cold, black backdrop of space, these space pioneers observed how beautiful, how warm and inviting, and yet how small and fragile our world seemed. Looking closer, they saw changes occurring, some rapidly and some slowly, all over the planet. EARTH'S ATMOSPHERE seemed to almost boil with activity as clouds formed and dissipated daily. Vortices of violent storms raged across the surface. Changes on land were evident as volcanic eruptions and large wildfires sent plumes of smoke high into the atmosphere. At night, the extensive spread of humanity could clearly be seen as clusters of city lights outlining the Earth's habitable land masses. Outer space, scientists found, is an ideal perspective from which to observe and measure changes on our home planet as they happen.

In April 1960, NASA launched the Television and Infrared Observation Satellite (TIROS) into a mid-latitude orbit around the Earth. Followed later that same year by TIROS II, and by TIROS III a year later, these were the first satellites designed to study Earth's rapidly changing weather patterns. They collected and beamed back to Earth thousands of images of cloud cover as well as images of hurricanes, tropical storms and weather fronts that might have otherwise gone undetected for days using conventional methods.

Over the decades, the art and science of space-based observations of the Earth expanded and evolved. Scientists developed satellite 'remote sensors' that are sensitive to regions of the electromagnetic spectrum other than visible light, allowing us to observe things we would not ordinarily see. For instance, designing TIROS II and subsequent satellites to measure infrared light (basically heat) enabled scientists to produce 'false color' images of clouds at night. ('False color' images are made by assigning red, green and blue values to differing wavelengths of radiant energy.) In 1964, the TIROS design was succeeded by the more advanced Nimbus series of weather satellites, and NASA began to explore other orbit strategies for its spacecraft. The Nimbus satellites flew in near-polar, Sun-synchronous orbits, allowing scientists to piece their data together into mosaic images of the entire globe. Other satellites, such as the 1966 Applications Technology Satellite (ATS-1), flew in 'geosynchronous' orbits, where they had fixed views over roughly the same spots on Earth throughout their lifetimes. The ATS-1 provided images over the same areas progressively every 30 minutes, providing meteorologists with more updates of changes occurring in near-real time. In May 1974, NASA launched the first in the series of geostationary weather satellites, called SMS-1. In October 1975, NASA launched the National Oceanic and Atmospheric Association's (NOAA) first Geostationary Operational Environmental Satellites

(GOES), each with a fixed and continuous view of the changing weather patterns beneath them. The GOES 8 and 10 satellites are still in operation, providing many of the daily weather images over North America that meteorologists display in their television evening news shows today.

Earth is a dynamic planet

Change is perhaps the only constant in our planet's history. Since the Earth's beginning about 4.5 billion years ago, natural climate and environmental conditions on our planet have been in constant flux. Solar variability, volcanic eruptions, meteor impacts, the emergence of life, the formation of an atmosphere rich in oxygen and greenhouse gases, changing ocean circulation patterns, wildfires—over the millennia these and other geological forces shaped an intricately intertwined global climate system that we are only just beginning to understand.

Fast forward to the late 1800s and witness the arrival of a new and profound force for change—humankind's Industrial Revolution. The Industrial Revolution not only ushered in a new era of prosperity for many, it also gave us the tools to dramatically reshape our environment. But the impact we are having on our environment appears to have set the wheels of climate change in motion at a rate not seen on Earth for millions of years. Over the last 100 years, the human population has tripled. In that time, we have consumed fossil fuels in increasing amounts to feed our rapidly industrializing economies, raising atmospheric carbon dioxide levels by 25 per cent. We have burned away forests to make room for our cities and roads, releasing carbon dioxide as well as eliminating trees that would otherwise be re-absorbing some of the gas from the air during photosynthesis. Over the last three decades, humans have burned more than 750 000 square kilometers of forestland every year. We introduced chlorofluorocarbons into the air, which destroy ozone in the stratosphere. Without its stratospheric ozone shield, the surface of our world would be exposed to the Sun's harmful ultraviolet rays, and life as we know it could not exist. Due, at least in part, to the rising levels of carbon dioxide, the average global temperature has risen by 0.5 ºC over the last century, and some computer models predict it could rise another 1 ºC over the next century. Already we see the polar ice caps melting at an alarming rate, while an average of two to three glaciers disappear worldwide every week. Geologists speculate that the US Glacier National Park will contain no glaciers by the year 2050. (See also GREENHOUSE EFFECT.)

What precisely are the causes of these changes? Which changes can be attributed to natural variability, and which are human-induced? How will these changes affect weather and climate patterns in the twenty-first century? How will climate and environmental change impact the quality of life for our grandchildren, and theirs? To help answer these questions and more, NASA developed a new series of satellite remote sensors, beginning with the Earth Resources Technology Satellite (ERTS) launched in 1972 (and later renamed Landsat 1).

From observing to measuring changes on Earth

Altogether, NASA launched a total of seven Landsats, the most recent, Landsat 7, was launched in April 1999. It and Landsat 5 are the only two of that series currently in operation. Since the first Landsat mission, the series' primary objective has been to measure changes on the land surface at high resolution. Whereas the first Landsat could collect images at about 65 m per pixel (at nadir), Landsat 7 can see the surface at resolutions as fine as 15 m per pixel. Such detailed imagery allowed scientists to find geologic features such as meteor impact craters previously undiscovered. Additionally, because healthy green plants reflect and absorb infrared light differently from dry brown plants, scientists found they could use Landsat data to monitor the health of croplands and forestlands over large areas. Landsat also provides an excellent data set for gauging the rates of deforestation, drying inland water bodies, expanding desert regions and sprawling urban centers. Researchers around the world routinely use Landsat data for these and myriad other applications.

In 1973, two researchers at the University of California, Irvine, published their theory that man-made chlorofluorocarbons (CFCs) could damage the Earth's stratospheric ozone shield. Two years later, Congress asked NASA to develop a 'comprehensive program of research, technology, and monitoring of phenomena of the upper atmosphere'. In particular, Congress' intent was to ascertain the 'health' of the ozone layer. In 1978, NASA launched the last of the Nimbus spacecraft series, Nimbus 7, carrying two new sensors called the Solar Backscatter Ultraviolet (SBUV) instrument and the Total Ozone Mapping Spectrometer (TOMS). Sensitive to radiant energy in the ultraviolet region of the electromagnetic spectrum, the Nimbus 7 sensors took advantage of the fact that molecules and aerosol particles reflect certain wavelengths of ultraviolet rays while ozone absorbs others at different levels in the atmosphere. By analyzing the amount of ultraviolet energy reflected back up to the spacecraft, researchers could produce profiles of how thick or thin the ozone was at different altitudes and locations.

But, ironically, the 'OZONE HOLE' over Antarctica was not discovered until May 1985, when a British researcher using a ground-based Dobson ozone spectrophotometer, found that stratospheric ozone over Halley Bay was about 40 per cent less than what had been measured during the previous winter. Surprised, NASA researchers hastily reviewed their TOMS data and

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

found that it too had detected a dramatic loss of ozone over all of Antarctica. Why had they not they discovered the phenomenon earlier? Unfortunately, the TOMS data analysis software had been programmed to flag and set aside data points that deviated greatly from expected measurements, and so the initial measurements that should have set off alarms, perhaps years earlier, were simply overlooked. In short, the TOMS team failed to detect the ozone hole because it was much more severe than scientists expected.

In the years following the discovery of the ozone hole, NASA satellites recorded depleting ozone levels over Antarctica that grew worse with each passing year. In response, in 1987, 43 nations signed the 'Montreal Protocol' in which they agreed to reduce the use of CFCs by 50 per cent by 2000. In 1991, NASA's Upper Atmosphere Research Satellite (UARS) mapped levels of chlorine monoxide in the stratosphere and quickly demonstrated that there is a direct link between the presence of chlorine, the formation of chlorine monoxide during winter in the Southern Hemisphere, and the destruction of ozone. Was a global disaster averted? Will levels of stratospheric ozone stabilize and return to normal in the coming years? We do not know yet, only time and more data will tell.

Towards predicting climate change

As we make the transition to the twenty-first century, the Earth's environment will be the focus of many agricultural, industrial, societal and political decisions. We recognize that we need more and better data to help us understand how current environmental change trends may impact climate years or even decades in the future. To collect these data, in 1991, NASA established the Earth Observing System (EOS) program in response to a US presidential initiative to provide in-depth scientific understanding about the functioning of the Earth as a system. The EOS charter is to collect, at a minimum, a new 15-year data set on which to base a long-term and comprehensive examination of our planet's climate system. EOS is a multinational endeavor comprising three parts: (1) a series of advanced satellite remote sensors; (2) a robust new computer network (called EOSDIS) for processing, storing and distributing EOS data; and (3) about 850 scientists working in many nations and in many Earth science disciplines who will use these new data in their research.

Already, NASA has launched four EOS spacecraft in the 1990s, including Landsat 7, QuikScat, ACRIMSAT and the EOS flagship, Terra, that was launched in December 1999. There are 15 more EOS satellites scheduled to launch through to 2003. Rather than focusing on individual disciplines, the data from these EOS satellites will be integrated into a more wholistic study of the Earth that includes seven overarching themes:

- radiation, clouds, water vapor, precipitation and atmospheric circulation;
- ocean circulation, productivity and exchange with the atmosphere;
- tropospheric chemistry and greenhouse gases;
- land ecosystems and hydrology;
- snow, ice and glacier extent;
- ozone and stratospheric chemistry;
- volcanoes and climate effects of aerosol.

With EOS, for the first time ever for a major Earth observation program, the goals include freely sharing the resulting data with both scientists and civilian organizations alike. This treatment of data contrasts sharply with previous satellite missions for which public access to data was quite costly. In fact, some EOS data are being directly broadcast to anyone anywhere who has a compatible receiving station and the capacity to process and store such a huge flow of information. As its name suggests, EOS is a large-scale, long-term collaborative mission involving scientists in government agencies, academia and industry from many nations.

Conclusion

Today, Earth scientists' goals are to not only observe weather patterns around our world, but to determine the causes and effects of climate and environmental change. With increasingly sophisticated satellite remote sensors, we can measure a wide range of geophysical parameters (such as surface temperature, distribution of clouds and aerosol particles, the abundance of trace gases in the atmosphere, or the distribution and types of life on land and in the ocean) with unprecedented accuracy and resolution. Moreover, we can now measure how changing certain aspects of the climate system (such as cloud cover) can have a 'ripple effect' through other aspects of the climate system (such as surface temperature, precipitation, the radiation budget). Scientists are feeding these new satellite data, collected throughout the Earth's climate system, into sophisticated new computer models that, ultimately, will enable them to predict climate changes months, years or even decades before they occur. If we are to become better stewards of our home planet—if we are to leave abundant natural resources to our grandchildren and to their grand-children—then we must continue monitoring our planet with satellite sensors ever improving our understanding of how the Earth system works.

Earth's Atmosphere

Composition and physical conditions of the neutral atmosphere

Our planet is surrounded by a thin envelope of gas, its atmosphere. This atmosphere, containing large amounts of molecular oxygen and therefore ozone, which protects us from the harmful solar UV radiation, and greenhouse gases like water vapor or carbon dioxide, maintaining mild climatic conditions, is unique in the solar system. It plays a crucial role in preserving at the surface of the Earth an environment suitable for the preservation and development of life, and must be considered as a key component of the Earth system. The average pressure at the ground level is 1013 mbar, with a column atmospheric mass of 1 kg cm^{-2} and a density of 2.7×10^{19} molecules/cm^3. The average temperature at the surface of the Earth is 288 K, or 15 °C. The atmosphere is mainly composed of molecular nitrogen (78.1%), molecular oxygen (20.9%) and less than 1% of argon, with an average molecular mass of 29 atomic mass units (table 1). A few precipitable centimeters of water are also present in the atmosphere, either as vapor or in the form of water droplets, or ice particles, in the clouds. The volume mixing ratio of water vapor is highly variable, but is everywhere less than 1%. Carbon dioxide, despite its small relative abundance (0.04%), plays a crucial role in the radiative budget of the planet. Minor constituents of Earth's atmosphere are listed in table 2.

The chemical composition of the atmosphere was discovered by the French chemist Antoine-Laurent de Lavoisier in the second part of the eighteenth century from the study of oxidation reactions. Lavoisier, at the same time as the English scientist Joseph Priestley, came to the conclusion that a particular constituent of air (oxygen) has the property of combining with metals to form oxides from which it can be released by heating. The existence of a second constituent (nitrogen), which does not enter the formation of oxides, was also required by experimental results. At this time, instruments for measuring the most basic physical properties of the atmosphere (temperature, pressure, rain, wind, humidity) had already been invented and the first systematic measurements of temperature were just beginning to be performed, for example at the Royal Meteorological Institute of the Netherlands. The vertical exploration of the atmosphere, first illustrated by Pascal's experiment on the Puy de Dome in 1647, was continuing with the help of kites and balloons: the first meteorological sounding, realized in 1783, reached an altitude of 3400 m. At the end of the nineteenth century, two French meteorologists, Hermitte and Besançon, performed systematic launches of balloons carrying pressure and temperature sensors. The stratosphere was discovered in 1899 by Léon Teisserec de Bort. During the twentieth century observations rapidly developed through the use of stratospheric balloons and airborne measurements, whereas in the most recent period, remote sensing from satellites has become the most powerful means of monitoring the global structure of Earth's atmosphere.

The vertical structure of the atmosphere is controlled by the law of hydrostatic equilibrium: density adjusts itself in such a way that the (downward) gravitational force is balanced by the (upward) force induced by the vertical pressure gradient. Assuming that air is a perfect gas, it can be shown that the atmospheric pressure decreases exponentially with altitude, with values of 100 mbar and 10 mbar at 15 km and 30 km altitude respectively. Considering its mass, Earth's atmosphere is equivalent to a homogeneous layer of 8 km thickness. Up to 100 km altitude, the atmosphere is mainly composed of neutral species. Constituents are mixed by turbulent viscosity, resulting from wind and wave activity, and the vertical distribution of each constituent does not depend on its own molecular mass. To a first approximation, the species which are not affected by condensation or chemistry, like molecular nitrogen, molecular oxygen and argon, have the same vertical distribution and are therefore uniformly mixed. The region below 90 km altitude, where constituents are uniformly mixed, is called the 'homosphere'.

Because the temperature decreases with altitude, as described later, and because the saturation pressure of water vapor is an increasing function of the temperature, the water vapor mixing ratio decreases with altitude and is only a few ppmv (part per million in volume) above 15 km. Another important example of a non-uniformly mixed constituent is ozone (O_3), whose abundance is controlled by chemistry. Ozone results from the dissociation of molecular oxygen by solar ultraviolet photons, which yields oxygen atoms able to form ozone by reaction with molecular oxygen. This reaction occurs between 15 km and 50 km in the stratosphere. Although the ozone mixing ratio does not exceed 0.1 ppmv, the ozone layer is quite an efficient shield against harmful solar ultraviolet radiation, because photons in the wavelength range 200–300 nm easily break down the ozone molecule. The quantity of ozone present in the stratosphere is equivalent to a 3 mm thick layer of pure ozone in STP conditions (standard pressure and temperature: 1013 mbar, 273 K). The presence of a well-marked stratosphere is an oustanding characteristic of Earth. The atmospheres of our two 'sister' planets, MARS and VENUS, which are not supplied with oxygen by photosynthesis, have no stratosphere.

Historically, ozone was measured for the first time at the beginning of the 1950s, by using the method of solar OCCULTATION. The earliest ozone measurements were obtained by the Naval Research Laboratory (NRL) using captured V2 rockets, which with their inertial stabilization offered an excellent platform. The occultation method consists of observing the Sun, or a star, setting or rising behind the limb of Earth. In this way, the absorption spectrum of the upper atmosphere can be observed as a function of altitude, yielding the vertical distribution of absorbing species. Accurate ozone measurements were obtained up to 70 km. The same method allowed

Table 2. Minor molecular constituents of the atmosphere. (From Banks and Kockarts (1973).)

Molecule	Ratio by volume	Remarks
CO_2	3×10^{-4}	Small variation
H_2O	10^{-2}–10^{-5}	Variable, particularly in troposphere
CH_4	1.5×10^{-6}	Fairly constant, mixed in troposphere
N_2O	2.5×10^{-7}	Approximately constant, mixed in troposphere
H_2	5×10^{-7}	Probably mixed in troposphere
O_3	10^{-8}–10^{-7}	Maximum in stratosphere
CO	5×10^{-8}–2×10^{-7}	Variable
NO_2	5×10^{-10}–2×10^{-8}	Variable, effect of NO

measurement of O_2 absorption as high as 140 km, whereas it was firmly believed that this gas was totally absent above an altitude of 90–100 km.

Above 90 km altitude, in the 'heterosphere', the different species separate from each other due to the effect of gravity. Viscous forces are no longer able to mix the constituents and each one distributes according to its own molecular mass. In this altitude range, the atmosphere is flooded with ultraviolet photons and energetic particles, and the atmospheric molecules are dissociated and ionized. Atoms, which are lighter than molecules, extend up to higher altitudes: atomic oxygen is the major constituent above 200 km altitude, whereas hydrogen, together with helium, dominates above 700 km. The average molecular mass of atmospheric molecules therefore decreases with altitude in the heterosphere. Ultimately, through their thermal kinetic energy, hydrogen atoms are able to escape from the terrestrial atmosphere in the upper regions where collisions are not frequent.

The general structure of the vertical temperature profile is given in figure 1. It is based on the nomenclature first introduced by Sydney Chapman in the 1930s. In the lower part of the atmosphere, below 10–15 km, termed the 'troposphere', the temperature decreases with altitude with an average rate of 6.5 °C km^{-1}, nearly equal to the humid adiabatic temperature lapse rate. The heat source is the surface, illuminated by the visible solar radiation. Heat is transferred to the troposphere through three different processes: evaporation of water and release of latent heat through the formation of clouds; infrared emission and absorption by greenhouse gases; and sensible heat flux. Vertical transport of water vapor and heat is ensured by convective motions. The transparency of Earth's atmosphere in the visible range, which allows most solar

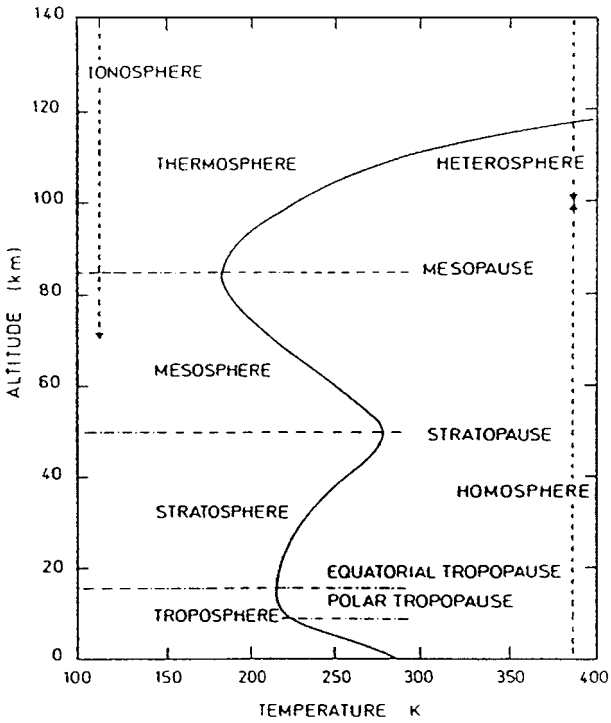

Figure 1. Thermal structure of Earth's atmosphere. (From Brasseur and Solomon (1994).)

photons to reach the ground, is a major determinant of the Earth's climatic system. On Venus, for example, the very dense lower atmosphere of carbon dioxide, with a pressure at the ground level of ≈ 90 bar, prevents the

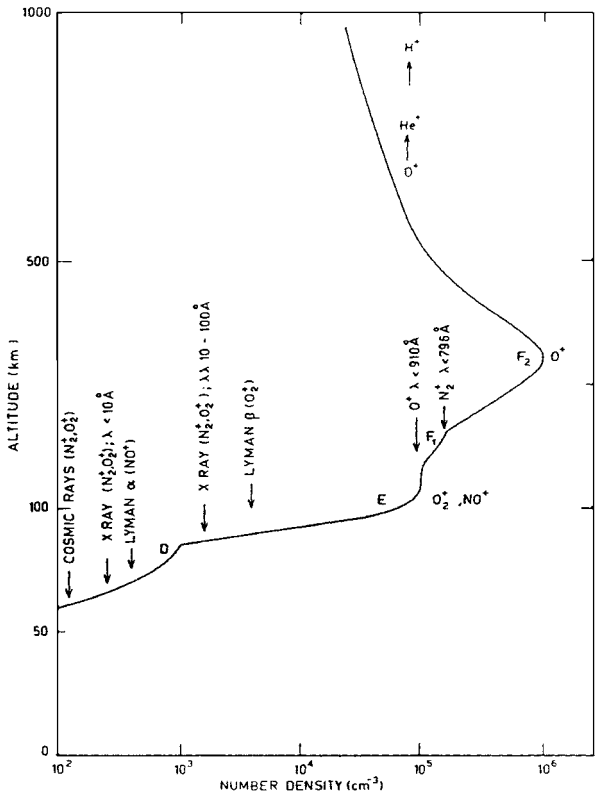

Figure 2. Average daytime electron distribution with principal ions in the various layers of the atmosphere. (From Banks and Kockarts (1973).)

solar visible radiation from reaching the ground, yielding a completely different behavior of the climatic system (see VENUS: ATMOSPHERE). Above 15 km, in the 'stratosphere', temperature increases from 220 K up to 270 K at 50 km altitude. The stratosphere is directly heated by the solar ultraviolet radiation, absorbed by ozone, whereas cooling occurs through infrared emission of carbon dixoxide, and to a lesser extent water vapor. Above 50 km altitude, in the 'mesosphere', the ozone concentration decreases and the temperature decreases regularly up to 90 km altitude, where it is less than 200 K. Above 90 km, in the 'thermosphere', the enhanced ultraviolet radiation results in an increase of temperature with altitude, with a high diurnal and seasonal variability due to the low thermal inertia of the tenuous atmosphere. Heat absorbed in the thermosphere is transported downward by thermal conduction and radiated in the infrared at the top of the mesosphere.

The ionized environment of Earth

The ionized atmosphere, or 'ionosphere', is composed of several well marked layers. This layer structure is due to the variety of ionizing fluxes (UV and x-rays, energetic particles) and ionized species. Although a few ions are present in the 60–80 km range, ionization is substantial only above 80–90 km. The main ionospheric layers are denoted by D, E and F. They extend from the base of the D layer, at 60 km altitude, up to 400 km, above the peak of the F_2 region, as shown in figure 2. The most deeply penetrating energy fluxes are cosmic rays, x- and solar Ly-α photons, which are responsible for IONIZATION in the D layer and are very sensitive to solar activity. Soft x-rays (λ = 1–10 nm) and long-wavelength UV radiation are the main ionization sources in the E layer. Major ions are atomic and molecular oxygen, together with nitrogen monoxide. Whereas O_2^+ and N_2^+ are created by ionization of the corresponding molecules, which are the dominant species, according to the following reaction scheme

$$O_2 + h\nu \rightarrow O_2^+ + e^-$$

NO^+ is formed through the charge-exchange reaction

$$O^+ + N_2 \rightarrow NO^+ + N.$$

The vertical distribution of ions is complex. O_2^+ and NO^+ dominate in D, E and F_1 regions, whereas O^+ is the major ion in the F_2 region. Above 1000 km, light ions like H^+ and He^+ are dominant. Electron density peaks at 300 km, with a maximum value of 10^6 cm^{-3}. This value presents a strong diurnal variability, due to the lack of solar photons during the night. At night, the electrons completely disappear in the D layer and their abundance considerably decreases in E and F_1 layers. The behavior of the F_2 layer is more complex, because transport by vertical diffusion and winds plays an important role in the topside ionosphere.

Historically, the role of the conductive ionized envelope of our planet in reflecting radio waves was discovered at the very beginning of the twentieth century. The first transcontinental radio communication was established by Marconi. At the end of the 1920s, Appleton in England and Tuve in the United States developed the first instrument dedicated to the teledetection of the ionosphere, the 'ionosonde', which dominated research on high atmospheric physics until the beginning of the space era. Modern ground-based observations of the physical parameters of the ionosphere (density, temperature, wind) use the technique of the 'incoherent scattering radar', which consists of illuminating the ionosphere by a radio wave beam and analysing the spectral characteristics of the scattered signal.

At increasing altitudes, the role of the Earth's intrinsic magnetic field becomes important. In the 'magnetosphere', the motion of particles is mainly controlled by electromagnetic forces (see MAGNETOSPHERE OF EARTH). Because the magnetic field deflects the charged particles of the SOLAR WIND, which blows from the dayside to the nightside with a velocity of about 400 km s^{-1}, it carves in the flow of the solar wind an elongated cavity. This cavity presents to a first approximation an axial symmetry around the Sun–Earth axis, contrary to the spherically symmetric low layers of the ionosphere. Its shape is

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

approximately parabolic in the solar direction, where it extends up to about 12 Earth radii. In the downwind direction, the magnetosphere is almost cylindrical and forms a magnetic tail with a length of several AUs (1 AU = 1 Astronomical Unit, that is the Sun–Earth distance, or 1.5×10^{11} m), which can be compared to cometary tails. The magnetosphere is composed of an extremely tenuous medium, with a typical density of one particle per cubic centimeter, where the collisions between particles play a negligible role. The inner boundary of the magnetosphere, the plasmapause, is located at about 4 Earth radii from Earth center in the equatorial plane. The region inside the plasmapause, called the 'plasmasphere', is filled with a relatively cold ($T < 10\,000$ K) and dense ($n \approx 100$ particles/cm^3) plasma originating in the ionosphere (see MAGNETOSPHERE OF EARTH: PLASMASPHERE).

A few of the incident solar wind particles (about 1%) penetrate the magnetosphere. Some of them precipitate at high latitude along the lines of the magnetic field lines and reach the low atmospheric levels: an electron of typical energy 10 keV can penetrate down to 100 km altitude before being substantially dragged. Precipitating energetic particles (mainly electrons) produce, through ionization of species like atomic oxygen, followed by recombination and fluorescence, the well-known and visually stunning phenomenon of auroras. The luminosity pattern of an AURORA, which reflects the shape of Earth's magnetic field lines, anchored in the deep Earth and disturbed at high altitude by the flow of precipitating particles, is extremely various, from quiescent, diffuse big auroras to the complex, beautiful patterns of auroral 'bands' and 'arcs'.

In a more detailed way, the primary electron is the source of many secondary electrons at altitude, through ionization reactions of the type

$$A + e^- \rightarrow A^+ + e^- + e^-.$$

Ionized species recombine, either by 'radiative'

$$A^+ + e^- \rightarrow A^* \rightarrow A + h\nu$$

or by 'dissociative' recombination

$$XY^+ + e^- \rightarrow X^* + Y^* \rightarrow X + Y + h\nu$$

by emitting photons. The most frequently observed emissions are the green and red lines of atomic oxygen at 558 nm and 630–636 nm respectively. A violet coloring, due to the N_2^+ line at 391 nm, may sometimes be observed. The red line of oxygen is produced by radiative de-excitation of the first excited state O(^{1}D) of oxygen. Because the radiative lifetime of O(^{1}D) is long, about 2 mn, fluorescence in this line cannot occur in the lower ionosphere ($z <$ 200 km), where the excited state is deactivated by collisions with air molecules in a time smaller than the radiative emission time. For this reason, red auroras occur only at high ionospheric levels.

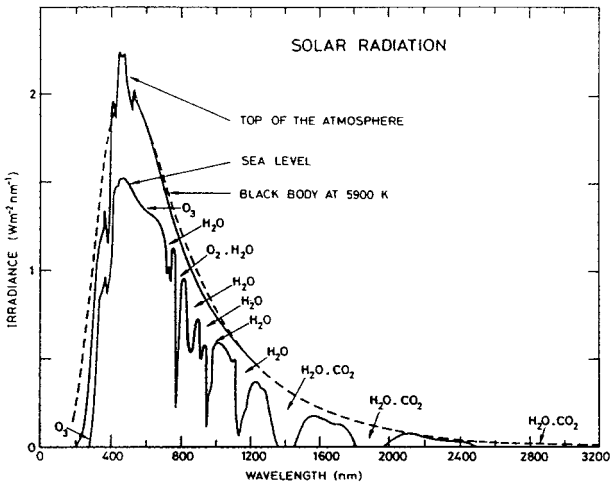

Figure 3. Spectrum of solar radiation outside Earth's atmosphere and at sea level, including comparison with black body radiation at a temperature of 5800 K. (From Banks and Kockarts (1973).)

Atmospheric absorption, scattering and scintillation

The UV and visible radiation of the Sun is partially or totally absorbed by Earth's atmosphere. At wavelengths of less than about 300 nm, stratospheric ozone molecules are easily dissociated by solar photons. At longer wavelengths, in the visible range where the solar radiation spectrum peaks, there is much less absorption, although some absorption occurs around 600 nm due to ozone. At wavelengths longer than 700 nm, absorption occurs mainly by excitation of vibrational (and rotational) levels of H_2O and CO_2 molecules, as well as O_2 in the forbidden band at 760 nm. As can be seen in figure 3, an extinction continuum is also present. It is due to the scattering of photons by air molecules, mainly N_2 and O_2, and cloud particles. The average reflectivity (or 'albedo') of Earth's atmosphere and surface is 0.3. Only 70% of incoming solar photons are absorbed by Earth's system, the remainder being scattered to space, principally by clouds which cover on average 50% of the planet.

In the field of astronomical ground-based observation, the phenomenon of ATMOSPHERIC REFRACTION, in the presence of turbulent motions, is also of great significance. The troposphere and stratosphere of the Earth are highly turbulent because of winds and wave activity: the kinetic energy of large-scale atmospheric motions (typically kilometric) is progressively transferred to small scales (typically millimetric), where dissipation occurs by viscous friction. This process is accompanied by local fluctuations of the density, therefore of the refractive index. The planar wave front received from a star is distorted as the light passes through the atmosphere. Both intensity and propagation direction are randomly modified due to the variations in the cross-sectional area and orientation of bundles of light rays. The fluctuations in the intensity are responsible for the well known phenomenon of SCINTILLATION which

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

results from traveling inhomogeneous air masses at altitude. The associated variations of the propagation direction yield a loss of angular resolution, which depends on the turbulent scales and their vertical distribution, as well as of wind patterns. It is theoretically shown and experimentally verified that atmospheric turbulence results in an angular dispersion, or 'SEEING', in the range from 0.2 to 1 arcsec, depending on the altitude of the observation site and local weather conditions. The seeing is therefore larger than the diffraction-limited resolution of a 1 m class telescope. The only way to overcome this intrinsic limitation is to use adaptative optics, the principle of which is to monitor the phase and adjust the mirror's shape in real time.

Global radiative budget and dynamics

Despite substantial atmospheric extinction, as previously described, Earth's atmosphere is largely transparent to solar photons in the visible part of the spectrum. As a result, the visible radiation of the Sun is mainly absorbed by Earth's surface. It causes heating of soil, water, vegetation and the adjacent air, resulting in the existence of a troposphere. The surface, which is heated, radiates at long wavelength, in the infrared portion of the spectrum, mainly from 7 μm up to 100 μm. Although the energy of the emitted infrared photons is not large enough to dissociate or ionize molecules, contrary to the solar ultraviolet radiation, it is able to increase the internal vibrational and rotational energy of absorbing molecules, principally H_2O, CO_2 and O_3. That excess energy is transferred to the main atmospheric molecules as kinetic energy by molecular collisions. Conversely, cooling of the atmosphere occurs through emission of radiation, due to molecular state transitions between vibrational and rotational levels. Some of this radiation is directed towards Earth's surface, resulting in a substantial GREENHOUSE EFFECT. In the absence of any atmosphere, the average surface temperature would be 255 K, well below the freezing point of water, and no life could exist. At ground level nearly as much radiation is received from the atmosphere, in the infrared, as from the Sun, in the visible. The very high temperature at the surface of Venus (470 °C) is mainly due to the strong greenhouse effect of the massive carbon dioxide atmosphere; the black body temperature of Venus at the top of sulfuric acid clouds where thermal photons are released to space is about −40 °C, lower than the black body temperature of Earth (−18 °C) because of the high reflectivity of Venus' clouds.

The dynamics of the low atmosphere, thermally and dynamically coupled with the oceans, is controlled by the redistribution of heat from low-latitude regions, where it is preferentially deposited by solar visible radiation, to the whole planet. Indeed, the infrared cooling is more uniformly distributed at the surface of the planet than solar heating, with an excess downward flux of radiative energy in the intertropical region and the reverse situation at high latitudes. The Earth can be compared to a Carnot machine, with both a warm source (low-latitude regions) and a cold source (high-latitude regions), which converts thermal energy into work. The mechanical energy produced is used for generating large-scale organized motions able to transport heat towards the poles. The efficiency of the machine is weak, much lower than the maximum value allowed by the laws of thermodynamics ($\approx$ 10%). For a flux received from the Sun of 340 W m^{-2} in global, diurnal and latitudinal average, the mechanical power required to maintain the large-scale circulation is only 2.4 W m^{-2}, that is an efficiency of only 0.7%. Despite this low efficiency, the terrestrial 'wind machine', which feeds the global hydrological cycle, is of prime importance for maintaining life at the surface of Earth.

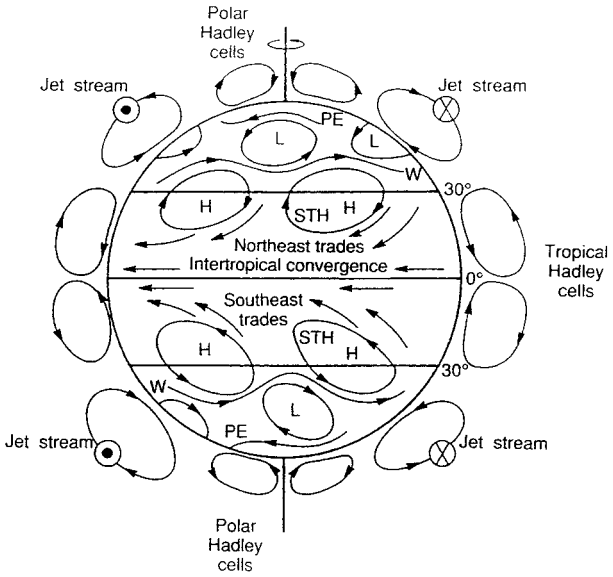

Figure 4. Principal features of the atmospheric circulation. (From Graedel and Crutzen (1993).)

Because the heating of the Earth by the deposited solar light is greatest at the equator, the hot equatorial air expands and moves upward. Consequently, air at low altitudes and from higher latitudes moves toward the equator to take its place. This equatorward flow is balanced by a return flow at higher altitudes, as summarized in figure 4. This poleward moving air progressively cools by infrared radiation to space. At about 30° latitude, the cooled denser air moves downward, closing what is called the 'Hadley circulation' on both sides of the equator. The equatorial upwelling branch of the Hadley cell occurs in the 'intertropical convergence zone' (or ITCZ). This is characterized by heavy precipitation due to strong upward convective motions, yielding massive water condensation and subsequent rain, and relatively low surface pressures. Condensation plays an important role in controlling and enhancing the tropical Hadley circulation, through the release of large amounts of energy (the 'latent heat of condensation'). On the other hand, the regions of subsiding air are much dryer and surface pressure relatively high. Due to the Coriolis force,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

which is associated with the rotation of the Earth and results in a deflection to the right of the direction of motion in the northern hemisphere and to the left in the southern hemisphere, equatorward motions of air in the tropical latitudes result in 'trade winds', blowing from the northeast in the northern hemisphere and from the southeast in the southern hemisphere. The flows at mid and high latitudes are much less regularly ordered than in the tropics because of the strong influence of travelling high and low pressure systems. Because of the Coriolis force, the winds tend to rotate clockwise around high-pressure systems (called 'anticyclonic circulation') in the northern hemisphere and counterclockwise in the southern hemisphere. Circulation around low-pressure systems ('cyclonic circulation') occurs in the opposite direction. In the mid-latitude regions, poleward heat transfer is ensured through sporadic air mass exchanges across 'warm fronts' and 'cold fronts'. This mechanism is due to the baroclinic instability, or literally 'pressure sloping instability', related to the horizontal temperature gradient, generating poleward motions of warm air and equatorward motions of cold air. Contrary to what happens in the tropical regions, the atmospheric flow at mid-latitudes is globally westerly (that is from the west). At higher altitudes, at the polar regions, heat transport is accomplished through the formation of cells rather similar to the tropical Hadley cells. It must be noted that about one-third of the poleward heat transfer takes place in the oceans.

The Martian climate, although colder, may be compared with the terrestrial climate. Global circulation on Mars also consists of trade winds in the intertropical zone and cyclonic/anticyclonic systems at mid-latitudes. This is due to similarities in the way in which the atmosphere is heated from below, as well as in the inclination of the rotation axis (23.5° for Earth, 25.2° for Mars) or the duration of the day, which differs by only 40 min (see MARS: ATMOSPHERE). Nevertheless, the absence of water oceans on Mars results in striking differences, like the development of a single Hadley cell with a wide rising branch over the summer hemisphere and a wide subsiding branch over the winter hemisphere, quickly reversing around the equinoxes.

The dynamics of the atmosphere is intimately coupled with the dynamics of the ocean, able to transport heat over large distances. Surface waters are dragged off along with winds and, because of heat exchanges with the atmosphere, modify the atmospheric thermal and wind regimes. One example of such a surface oceanic current is the Gulf Stream. Westerlies at mid-latitudes push surface water to the east, whereas easterly trade winds in the ITCZ act in the opposite way. This results in a clockwise rotation of water bodies, with a northward warm current along the eastern coast of America. During winter, cold and dry continental air coming from the west is heated and loaded with moisture when passing over the Gulf Stream, which results in strong perturbations and snow falls. The dynamical interaction between the atmosphere and the ocean at low latitudes may have dramatic consequences, mainly through the combined actions of evaporation and atmospheric convection, yielding the formation of vigorous cumulonimbus convective cells, or 'hot towers' (figure 5), pumping air and moisture upward and associated with massive rainfalls, lightning (which is electrical discharges between the positively charged upper layers of clouds and negatively charge lower layers, or Earth's surface) and winds. Such systems, associated with strong perturbations of the pressure field, sometime become hurricanes and tornados, rapidly rotating under the effect of the Coriolis force.

Figure 5. *Challenger* Space Shuttle orbiter photo showing a system of cumulonimbus clouds.

One of the most important, planetary scale, phenomena resulting from the interaction between the ocean and the atmosphere is the El Niño southern oscillation (ENSO). In normal conditions, trade winds push equatorial pacific waters from the Peruvian coasts to Indonesia. Surface waters are progressively heated during their slow westward migration through the Pacific ocean and reach a temperature of 29 °C near Indonesia, which results in a strong longitudinal thermal contrast. The ENSO phenomenon, which is still incompletely understood, is provoked by a weakening of trade winds, therefore thermal contrast, with a subsequent warm eastward countercurrent. This current, episodically appearing near Peruvian coasts right after Christmas (hence, the reference to 'the child'), is well known by the fishermen of this area, and is associated with massive rains. In the 1920s, Sir Gilbert Walker, director of the Indian Meteorological Office, found evidence of an anticorrelation between the atmospheric pressure in Tahiti, in the central Pacific, and the pressure in Darwin, in Australia. In 1969, J Bjerkness established the link between the warm oceanic countercurrent and the associated meteorological perturbations. Cumulus systems normally present over Indonesia are displaced several thousands of kilometers to the east, which tends toward amplifying, and sometimes reversing, trade winds. This positive retroaction ef-

fect yields dramatic consequences, with severe drought in Indonesia and heavy rains in Ecuador and northern Peru.

Biochemical cycles of main atmospheric species

From a chemical point of view, the atmosphere of the Earth is strongly coupled with Earth's solid and liquid surfaces through a variety of biogeochemical cycles. Earth's atmosphere is generally supposed, although this is still a controversial question, to have been outgassed from the interior, in a short episode of intense differentiation in the first 100 million years of Earth's life, 4.5 billion years ago. The primitive Earth atmosphere contained mainly carbon dioxide and water vapor, with possibly some traces of methane and other reduced gases. It is thought that a substantial amount of water may have been brought by comets and meteorites over a rather long period of time after accretion (a few hundred million years) and it is not excluded that Earth's atmosphere is partly of cometary and meteoritic origin. Oxygen at present contained in our atmosphere is the result of photosynthetic activity in the biosphere. It progressively accumulated in the atmosphere during the Precambrian era and reached its present level 300 million years ago, when the first land animals appeared. The atmospheric oxygen content is thought to be regulated by the action of marine photosynthetic activity, which removes a small fraction of carbon from the atmosphere through the formation of organic reduced carbon, a very small part of which precipitates downward through the ocean and is finally incorporated into sea-floor sediments. Oxygen atoms left behind by reduced carbon, which is trapped in sedimentary rocks for typical times of a few hundred million years (due to sea floor expansion), are responsible for the presence of a permanent oxygen atmosphere on Earth. Ultimately, reduced carbon is rejected by volcanoes or resurfaced metamorphic rocks above subduction zones and oxidized by the atmosphere, closing the cycle.

Similarly, the 'oceanic biological pump' plays a crucial role in regulating the atmospheric content of carbon dioxide, through the so-called 'carbonate–silicate' cycle. Carbon dioxide is released by volcanism and metamorphic processes from the solid Earth to the atmosphere and ocean at a rate which is estimated to be large enough to double the amount of carbon in the ocean and atmosphere in a few hundred thousand years. It must be noted that the terrestrial ocean contains much more carbon dioxide than the atmosphere (40 000 Gt versus 750 Gt; $1\ \mathrm{Gt} = 10^{12}$ kg). The carbon contained in carbonate rocks, if entirely released to the atmosphere, would represent $\approx$ 50–100 bar of CO_2, which is similar to the present content of the Venusian atmosphere. Due to the rapid exchange of CO_2 between the atmosphere and the ocean, the residence time of a CO_2 molecule in the atmosphere is less than 10 years (less than 1000 years in the ocean). For this reason, the ocean and the atmosphere must be treated as a single reservoir when studying their interaction with the solid planet, which acts over much longer time scales. Because carbon dioxide is released to the atmosphere, it must be returned to the solid Earth at an equal rate. The mechanism of this return is well known. It is the weathering of silicate minerals by rain water, containing dissolved carbon dioxide, followed by the deposition of carbonate minerals in sedimentary rocks. Cations produced by silicate weathering (Ca^{2+}, Mg^{2+}) are carried by rivers to the oceans, where they react with carbonate ions (CO_3^{2-}) to precipitate as carbonate minerals. In this way, oxidized carbon is trapped in sea-floor sediments in the form of limestone. Because the rate of supply of cations by weathering strongly depends on humidity and temperature conditions, and because CO_2 is a greenhouse gas, it is thought that this cycle has a controling influence on the budget of carbon in the combined atmosphere–ocean system.

In spite of the assumed stabilizing effect of the carbonate–silicate cycle over geological times, climatic conditions on Earth must be regarded as having evolved through a number of different stages over a long period of time. An example of global climatic instability is provided by the glacial–interglacial cycles which occurred during the Quaternary. The chemical composition and temperature of the ancient atmosphere may be retrieved from ice cores drilled on the Antarctic glacier. It is possible to trace back the Earth's climatic history during the last few hundred thousand years. Periodicities of 100 000, 41 000 and 23 000 years are evidenced and, as primarily inferred by Milankovitch, they are the consequences of variations in the motion of Earth through space. Orbital variations may be described by three parameters: the degree of ellipticity, the angle of tilt between the axis of rotation of Earth relative to the Earth–Sun orbit and the orientation of the axis of rotation with respect to the orbital path, which varies because of the precession phenomenon. All these three parameters undergo predictable changes due to the gravitational attractions exerted by the Sun, the Moon and the planets. These long-term variations modify the spatial and seasonal sequences of solar energy deposition at the surface of our planet, resulting in variations of Earth's climate. For example, at the end of the last glacial period, about 10 000 years ago, the inclination of the Earth's rotational axis relative to the ecliptic plane was about 24.5° (at present 23.5°) and the closest approach of the orbiting Earth to the Sun occurred in July (at present January). This past condition resulted in about 8% more solar radiation reaching the northern hemisphere in the summer and about 8% less in winter time. Although the astronomical effects are weak by themselves, they are relayed by strongly nonlinear feedback effects which result in large-amplitude climatic variations. Besides, the climate is also thought to exhibit large variations by itself, without any changes to astronomical effects.

Effects of anthropogenic activities on climatic evolution and atmospheric composition

It is thought that anthropogenic activities, responsible for a rapid increase in gas and particle emissions in the atmosphere, are potentially able to destabilize the global

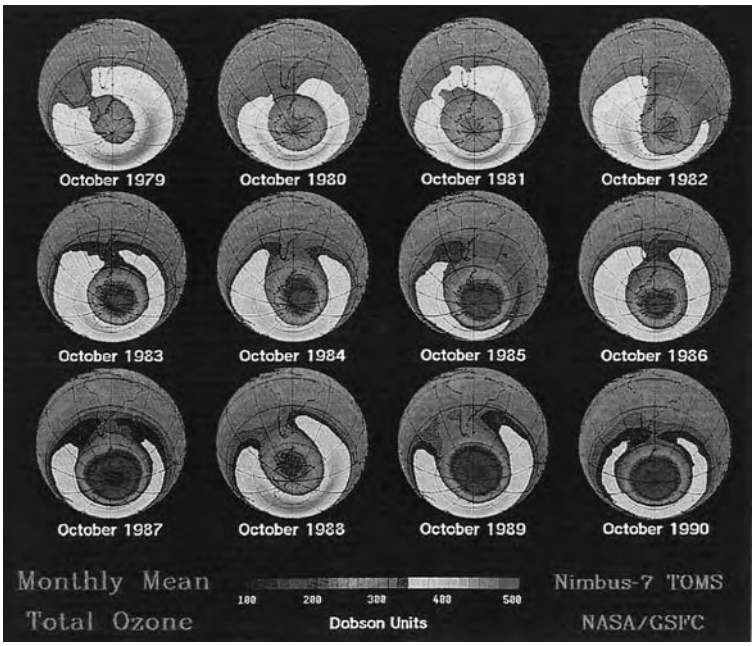

Figure 6. Total column ozone concentrations (in Dobson units; 100 Dobson = 1 mm thick layer of pure ozone in STP conditions) over Antarctica as determined by TOMS (Total Ozone Monitoring Satellite) during October from 1979 to 1990. (From Graedel and Crutzen (1993).)

climate of Earth. The carbon dioxide content of the atmosphere has increased from 275 ppmv at the end of the eighteenth century up to 350 ppmv at the present time. This increase is due to a variety of worldwide human activities. Until about 1950, the release of CO_2 was mainly due to the oxidation of organic matter in agricultural soils. Currently, the largest net source of CO_2 is fossil fuel combustion. Tropical deforestation also contributes to the atmospheric increase, although to a lesser degree. Because carbon dioxide is a greenhouse gas, this increase is expected to enhance the infrared opacity of the atmosphere, resulting in an increase of Earth's surface temperature. In addition to this direct effect, related secondary effects could play an important role, like the expected increase in the water evaporation rate, yielding both an additional warming, because water vapor is a greenhouse gas, and a counteracting cooling due to the increase of cloud cover and therefore of the average planetary albedo. It is emphasized that H_2O is the most important greenhouse gas, blocking the infrared radiation from Earth's surface more efficiently than CO_2 does. The temperature record for the past century shows that about 0.5 °C of warming has occurred in the last 130 years and that the last two decades were the warmest during this period. Although some natural variability cannot be excluded, it is thought that this general warming is the consequence of the regular atmospheric CO_2 increase.

Another consequence of anthropogenic gaseous emissions is the decrease of the stratospheric ozone content, due to the destructive action of chlorine contained in CFCs (chlorofluorocarbons). CFCs (mainly $CFCl_3$ and CF_2Cl_2) are not broken down in the troposphere. Over a period of a few years, these very stable gases move from their release point at the surface up in the stratosphere, where the solar ultraviolet radiation is intense enough to break them and release active chlorine species (Cl, ClO), able to destroy ozone. Satellite observations, performed since the beginning of the 1980s, show that stratospheric ozone regularly decreases at a global scale, with a rate of a few per cent per decade. This decrease is attributed to the action of CFCs. It has been decided at the Montreal Conference of 1990 to stop the emission of CFCs, but the long characteristic time of this destructive process prevents any significant improvement being obtained before the middle of the next century. The most dramatic illustration of stratospheric ozone destruction is the Antarctic 'OZONE HOLE', a rapid and accelerating decrease in the ozone over the Antarctic each September and October. The decrease in total ozone content may reach a factor of three. As soon as it was discovered, in 1985, attention was focused on the possibility of an enhanced chlorine destruction cycle, which was rapidly confirmed by observations and experimental work.

The strong decrease of stratospheric ozone over the Antarctic during the austral spring, which is illustrated in figure 6, is due to the very low temperatures occurring in the polar stratosphere of the southern hemisphere. During the polar winter, in the absence of solar radiation (from June to September), the temperature in the stratosphere can be as low as −85 °C, because polar air is enclosed in the 'polar vortex', a very large whirlwind which develops during winter over the polar regions. These

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

very low temperatures are responsible for the formation of 'polar stratospheric clouds' (or PSCs). These clouds are composed of pure water or mixed water/nitric acid ice. The surfaces of the PSCs serve as reaction sites for chemical processes able to transform unreactive chlorine species to reactive ones. These catalytic processes take place during the four months of the polar night and produce, from inactive HCl and $ClONO_2$ species, large quantities of HOCl and Cl_2 (see later). The combined effects of denitrification, through freezing and sedimentation of HNO_3 crystals, and chlorine radicals released at sunrise (Cl, ClO) from the photodissociation of HOCl and Cl_2, yield a massive destruction of ozone in the polar vortex. Incidently, other anthropogenic constituents, like bromine, play a similar, although less pronounced, role in the destruction of stratospheric ozone.

At stratospheric levels, the photodissociation of molecular oxygen by ultraviolet radiation at wavelengths of less than 240 nm produces atomic oxygen, which further combines with molecular oxygen to produce ozone

$$O_2 + h\nu \rightarrow O + O$$
$$O + O_2 + M \rightarrow O_3 + M.$$

Ozone is rapidly photodissociated back to atomic oxygen by photons in the wavelength range 200–300 nm

$$O_3 + h\nu \rightarrow O_2 + O.$$

'Odd oxygen' species (O, O_3) may recombine together according to the reactions

$$O_3 + O \rightarrow 2O_2$$
$$O + O + M \rightarrow O_2 + M.$$

The previous cycle, first identified by Sydney Chapman in the 1930s, must be completed by a set of other catalytic cycles evidenced in the last 20 years. A few minor constituents play a crucial role in destroying atmospheric ozone through catalytic cycles of the following type

$$X + O_3 \rightarrow XO + O_2$$
$$O_3 + h\nu \rightarrow O + O_2$$
$$O + XO \rightarrow X + O_2$$
$$\text{net: } 2\,O_3 + h\nu \rightarrow 3\,O_2.$$

Along this chain, the radicals X and XO catalyse the conversion of O_3 into O_2. The produced oxygen atom regenerates the catalyser X. The Chapman cycle is obtained for X = O. The hydroxyl radical, produced by the photodissociation of water vapor molecules, also plays a significant role (X = OH). Paul Crutzen found in 1970 that nitrogen oxides NO and NO_2 (X = NO), partly produced by agricultural activities and fossil fuel combustion, are quite efficient catalysers for ozone destruction. Mario Molina and Sherwood Rowland, who obtained together with P Crutzen the Nobel Prize for chemistry in 1995, have exhibited the crucial role of chlorine contained in CFCs on the chemistry of stratospheric ozone. Cl and ClO released by CFCs in the stratosphere are found to be still more efficient than NO in destroying ozone, through the previously mentioned catalytic cycle (X = Cl). Numerical models of stratospheric chemistry have been constructed in order to examine the consequences of all cycles previously described on the long-term evolution of ozone. The decrease of stratospheric ozone measured during the last 15 years is globally well reproduced by these models.

Earth's Interior

The interior of the Earth can be most simply described as a series of concentrically nested spheres, the main ones being, from the outside in, the CRUST, MANTLE, and CORE. This gross structure, recognized by seismologists early in the twentieth century, appears to be analogous to that of most silicate bodies—planets, satellites and probably the asteroids or their parent bodies—except the very smallest. The process of DIFFERENTIATION, by which these zoned structures were developed, probably resulted from extensive melting very early in the history of the solar system. The discovery that solid bodies are grossly differentiated was one of the most important geological findings of twentieth century space exploration, beginning with the Apollo expeditions to the Moon.

The Earth's interior will be described from the outside in, which is also the order of decreasing knowledge. The crust is now rather well-understood, or at least well described; the mantle can be described within certain constraints; and the core is understood least of all. Knowledge of the interior comes from a wide range of sources. The exposed interior is roughly the province of *geology*; study of the hidden interior, obviously almost the entire volume of the Earth, is the province of *geophysics*. Geologists study what can be seen, geophysicists what cannot, although there is complete overlap between the two fields.

Crust

There are two main divisions to the Earth's crust (figure 1), oceanic and continental. Continental crust can be summarized, simplistically, as old, thick and granitic. Oceanic crust can similarly be summarized as young, thin and basaltic. Furthermore, the oceanic crust is demonstrably mobile; as shown on the map, it is forming continuously by basaltic volcanism along mid-ocean ridges, and moving away from these ridges by the process of sea-floor spreading.

The outline just given of the Earth's crust is a subset, so to speak, of an even broader scheme, the now well-known theory of plate tectonics, which arose within about two years in the mid-1960s by the sudden coalescence of several lines of evidence. The Earth's crust, or more correctly its *lithosphere* (whose definition will be given shortly), is now believed to consist of a number of *plates*. Plates are segments of the lithosphere, relatively inactive and rigid, bounded in the simplest examples (e.g. the Nazca Plate) by some combination of oceanic ridges (or spreading centers), transform faults and subduction zones. The salient aspect of plate tectonic theory is that these plates are considered to be mobile, moving horizontally more or less in the manner proposed by Alfred Wegener in his classic continental drift theory. Plate tectonics alone fills many books, but its main features can be understood with the aid of figure 1. To begin our descent into the interior of the Earth, let us examine the vertical structure of the continental crust (figure 2).

Continental crust is an infinitely complex collection of igneous, sedimentary and metamorphic rocks. However, the cross section in figure 2 is offered as representing the most important features of the oldest and most fundamental part of this crust, the granite-greenstone terrains of Precambrian (older than about 600 million years) areas such as the Canadian Shield. Relatively few people have more than glimpsed such terrain, and even most geologists have only a general acquaintance with it. The reason is basically that continental crust as a whole is largely blanketed with relatively young rocks, such as the sandstones, shales and limestones exposed in the walls of the Grand Canyon. Furthermore, even Precambrian shields are criss-crossed with Proterozoic (2.5 billion- to 600 million-year-old) mountain belts or roots thereof. However, underlying most such mountain belts is rock of the sort shown here. Granite is the familiar pink igneous rock found on building fronts, cemetery headstones and monuments. Greenstone, less familiar, is essentially a greenish assemblage of metamorphosed volcanic rocks, originally basalts and related types.

The continental crust is thus underlain in most areas by rocks of the granite-greenstone type. From top to bottom, one will encounter successively belts of metamorphosed volcanics (greenstones), intruded by granitic rocks (many of which are not granites in the strict petrographic sense). At greater depths, these rocks are succeeded by what appear to be the metamorphic equivalents of granites, greenstones and sedimentary rocks, collectively termed granulites. These are dense, thoroughly recrystallized and highly deformed rocks.

A recent discovery, from seismic reflection profiling, is that unlike upper crustal rocks, and obviously unlike the deformed rocks of mountain belts, the lower crust granulites are largely flat-lying or within 20 to 30 degrees of the horizontal. These granulite layers were probably formed by a combination of deformation and recrystallization, acting on what were originally layers of sedimentary or volcanic rock. Readers in the United Kingdom can see (weather permitting) outstanding exposures of granulite along the northwest Scottish coast, around the village of Scourie.

The base of the continental crust is the Mohorovičić discontinuity, discovered by the seismologist of that name early in the century. The Moho, as it is commonly called, typically occurs at depths of 40 kilometers, but in areas such as the Andes or the Tibetan Plateau the crust is much thicker and the Moho may be 70 km or more deep. It is generally believed to be a compositional boundary, marked by a sudden increase in density as indicated by the increasing velocity of seismic waves. However, there is much to learn about this widely known boundary.

Oceanic crust differs from continental crust in almost every way. Its gross composition is basaltic, the basalt occurring, from the surface down, as lava flows, dikes (nearly vertical, sheet-like intrusive bodies), and near the base of the crust, the metamorphosed equivalents of these basaltic rocks. Newly formed oceanic crust can be seen

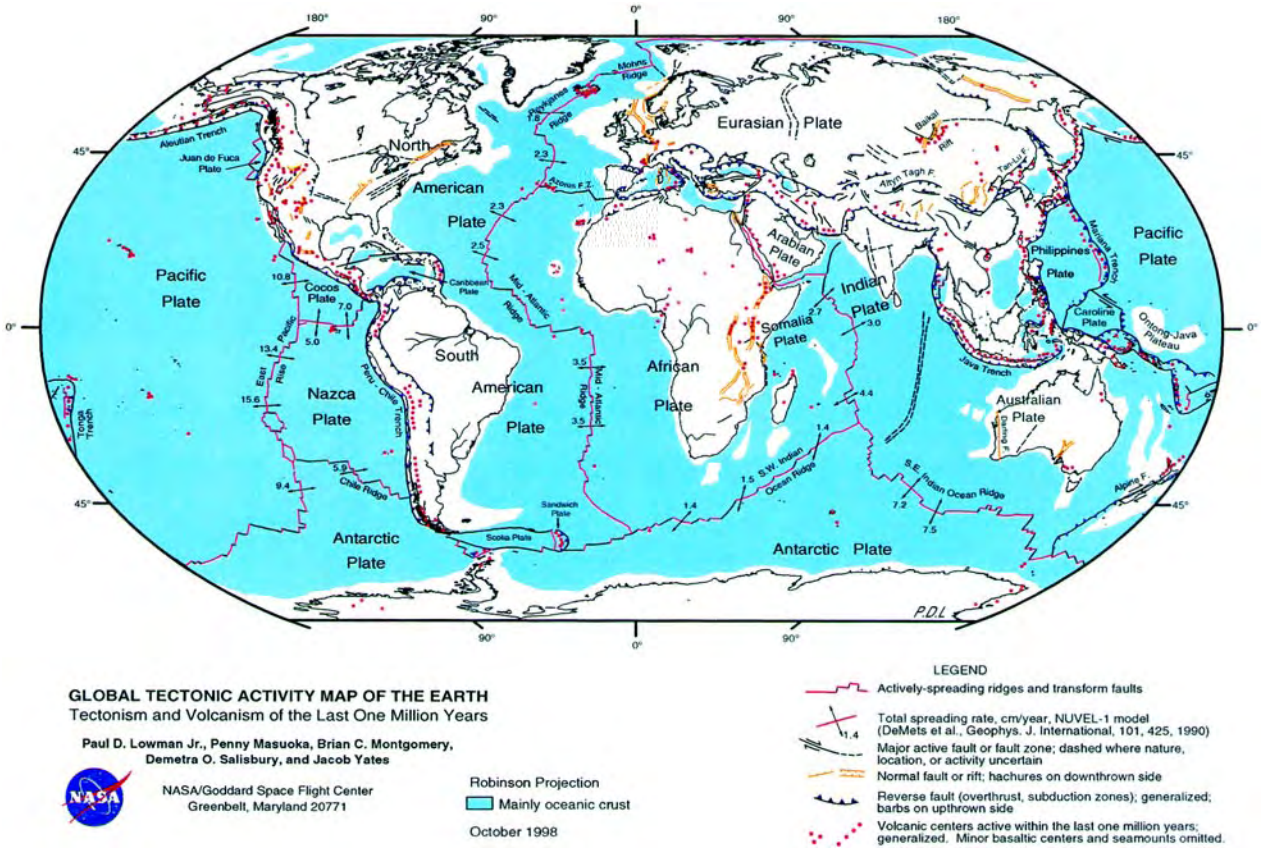

Figure 1. Tectonic and volcanic activity map of the Earth, covering the last one million years. Modified from Lowman (1982). **This figure is reproduced as Color Plate 24.**

in places like Iceland, located on the Mid-Atlantic Ridge. The crust under ocean basins is typically much thinner than under continents, the Moho generally lying at depths of 5 to 10 kilometers.

The origin of the oceanic crust is now, we believe, fairly well understood, an understanding that even skeptics will concede to be a major triumph for plate tectonic theory. In the context of this article, the dominant characteristic of oceanic crust is its youth and mobility. Because oceanic crust is eventually recycled through the mantle in subduction zones (figure 1), very little of it is more than about 200 million years old, in contrast to the 4 billion year age of the oldest exposed continental rocks, the Acasta Gneiss in Canada.

Mantle

Let us begin our descent into the mantle by returning to the deferred definition of *lithosphere*. The term crust is both a compositional and mechanical one, referring to the boundary between the silica-rich rocks of the crust and the silica-poor, iron- and magnesium-rich, rocks of the mantle. The term lithosphere in contrast is essentially a mechanical one, referring to an outer layer of the Earth that is relatively strong, elastic and rigid. This lithosphere includes, and is much thicker than, the crust.

Under ocean basins it varies from nearly zero at mid-ocean ridges to, very roughly, 50 to 100 km near subduction zones (where the oldest crust descends). However, under the old and stable parts of continents, such as the Canadian Shield, the lithosphere is much thicker, at least 200 km and in some estimates considerably more. Although the essence of the definition is mechanical, the subcontinental lithosphere in particular may have formed by extraction of basaltic magmas through geologic time, thus having a compositional connotation. In plate tectonic theory, horizontal crustal motions such as sea floor spreading and continental drift are considered the expression of motions (geometrically, rotations on a sphere) of the lithosphere, the thinner included crust being carried along with this lithosphere. (The term *plate*, to remind the reader, refers to the lithosphere, not just the crust.)

Below the lithosphere lies the *asthenosphere*. It is here that our ignorance of the Earth's interior becomes acute, for the thickness and extent of the asthenosphere, and in fact its very definition, are controversial. Physically, the asthenosphere is defined as a weak zone, or shell, characterized by low rigidity and strength, expressed as a decrease in the velocity of seismic compressional ('P') waves. In classic geophysics, the asthenosphere was

considered the zone of flowage responsible for the well-known post-glacial rebound of Scandinavia and northern Canada. In plate tectonic theory, it is thought to be the low-resistance layer on which plates move. Several lines of evidence indicate that the asthenosphere is largely a thermal feature, related to either partial melting or at least decreased shear strength expressing increasing temperature with depth. However, some geophysicists, partly because of the relationship of asthenospheric depth to oceanic crust age, define it on the basis of geochemical characteristics that will not be covered here.

Our descent into the mantle will be guided by P J Wyllie's comprehensive diagram (figure 3), showing the main inferred characteristics of the Earth's interior all the way to the center some 6300 km down.

The composition of the mantle has been very slowly uncovered by a century of work in several fields. Since it is exposed almost nowhere—and there only in limited, highly metamorphosed form—mantle composition has been an unusually difficult problem. Some volcanoes bring up samples from depths of perhaps 200 kilometers, diamonds being the celebrated example, but these are our only direct source of knowledge. Seismic properties have traditionally been the main basis for estimates of mantle composition, although they provide essentially only constraints on composition. Basaltic and related magmas are clearly of mantle derivation, and some 75 years of theoretical and experimental petrology pioneered by N L Bowen in the 1920s have, combined with other lines of evidence, led to fairly detailed profiles of the mantle, shown in figure 3.

The upper mantle is believed to consist of iron- and magnesium-rich rocks similar to those found at the surface, with names unfamiliar even to many geologists, such as lherzolite. However, as shown in figure 3, pressure increases rapidly with depth; a thousand kilometers down, the pressure is roughly half a million times atmospheric pressure at the surface. With increasing pressure, minerals invert to a series of denser and denser polymorphs (i.e. same chemical composition, but different crystal structure), such as perovskite (an iron-magnesium silicate). They may dissociate to form new mineral assemblages, that is, new rocks of varieties never found at the Earth's surface.

These phase changes are the result of the increase in pressure and temperature. The melting point of most solids is raised by increasing pressure, in a complex way, and it is believed that the mantle is close to its melting curve below the asthenosphere. There are several seismically identified discontinuities in the mantle, of which the one 650 km down is the most prominent. This discontinuity, actually a zone some tens of kilometers thick, is thought by most petrologists to represent the transition from lherzolite to perovskite. Regardless of its actual nature, this discontinuity is geophysically important as the boundary between the upper and lower mantle.

One of the most controversial topics in geophysics is the nature of motion in the Earth's mantle. It has been speculated for most of the century that despite its solid nature, the mantle is in slow continuous motion, specifically by thermally driven convection currents. The confirmation of crustal mobility in the form of sea-floor spreading, and other lines of evidence, has greatly strengthened the concept of mantle convection. However, it is by no means clear just what pattern or patterns such currents follow. It was originally proposed, in the 1930s, that the entire mantle was convecting, a view still held by many eminent geophysicists. However, the 650 km discontinuity is clearly a density barrier to whole-mantle convection. The pattern may consist of upper and lower mantle convection cells.

Another complication is the possible existence of more localized mantle motions, plumes of hotter material rising slowly through the mantle, perhaps analogous to the popular 'lava lamps'. There is good seismic evidence for at least some mantle plumes, for example under the volcanically active Yellowstone National Park. However, it is not known where such plumes originate; some workers consider them to begin at the core–mantle boundary, and to rise some 2900 km almost to the Earth's surface.

One of the longest-known and best-confirmed phenomena of plate tectonics is subduction, the downward movement of slabs of oceanic crust and lithosphere complementary to sea-floor spreading (where crust is created, as shown on figure 1). These slabs must sink to several hundred kilometers depth, inverting to denser phases as they go, and contributing to the heterogeneity of the mantle. Subduction thus has the interesting implication that surficial geologic processes can influence the nature and behavior of the mantle at enormous depths.

Core

It has been known for centuries that the interior of the Earth must be much denser than the crust, since the specific gravity of the entire globe is about 5.5, in contrast to that of, for example, granite, which is about 2.8. Striking confirmation that the Earth could not be granite all the way through was provided by the discovery that RADIOACTIVITY was a major source of heat in the Earth. But the radioactivity of granite in the crust alone was enough to account for observed heat flow, which would be enough to melt the interior if it were all granite.

Seismologists Gutenberg and Weichert identified a major discontinuity about 2900 km down early in the twentieth century, which was rapidly recognized as the boundary of a discrete core. Its physical properties corresponded roughly to that of iron, and the existence of iron METEORITES demonstrated that iron could be segregated in the center of a planet. The core does not transmit shear waves, leading to the conclusion that it was liquid. However, further seismologic studies by I Lehmann in the 1930s showed that the inner part of the core, below about

5000 km depth, was solid, an iron (presumably) sphere roughly the size of the Moon.

This general physical picture of the Earth's core is agreed upon by most geophysicists. However, continuing progress in seismology and geomagnetism are refining it rapidly. The main geomagnetic field is now plausibly explained as the result of convection currents in the liquid outer core, which, cutting the lines of force of the Earth's field, constitute a self-regenerating dynamo mechanism. This is not perpetual motion; interested readers should consult the listed references.

There is now evidence that the core–mantle boundary has considerable relief, on the order of a kilometer, perhaps related to the rise of mantle plumes if such do in fact exist. These irregularities may cause slight but real variations, over periods of years, in the EARTH'S ROTATION. It may be

helpful to visualize the Earth not as a solid rotating sphere, but as two such spheres, the inner one being the Moon-sized solid core separated from the outer one (the solid mantle) by the liquid segment of the core. Complications in the motion of such a decoupled system can easily be imagined.

Estimates of core compositions have been considerably refined; nickel is almost certainly a major alloying element, with traces of other siderophile elements such as platinum that are depleted in the Earth's crust and upper mantle. There are also probably substantial amounts of a lighter alloying element in the core, probably oxygen or silicon.

Summary

Our knowledge of the interior of the Earth has increased enormously through the twentieth century. Furthermore, we now know something of the interiors of other planets, providing the basis for comparative studies (see PLANETARY INTERIORS). However, the interior below a few tens of kilometers will be inaccessible to direct study for centuries to come, perhaps forever, and study of the inside of the Earth will be a fruitful field for geophysical research for many years to come.

Earth's Rotation

In the absence of internal or external perturbation, the Earth would rotate in space around its center of mass at a uniform angular velocity and around a fixed rotation axis lying at 23°26′ with respect to the ecliptic pole axis and directed approximately towards the northern star. The mean motion is a rotation in space every 23 h 56 min 4.10 s but, in reality, the Earth being composed of various non-rigid parts and not being isolated in space, the rotation is perturbed by a wide variety of geophysical and astronomical processes. These perturbations can be investigated in terms of causes and effects and are subject to theoretical investigations (see also EARTH'S ROTATION: THEORY).

Irregularities of the Earth's rotation—historical perspective

It is worthwhile to approach the Earth's rotation from a historical perspective. The chronology of the discovery of the Earth's rotational irregularities also reflects the progress of astrometric and geodetic techniques and time measurement.

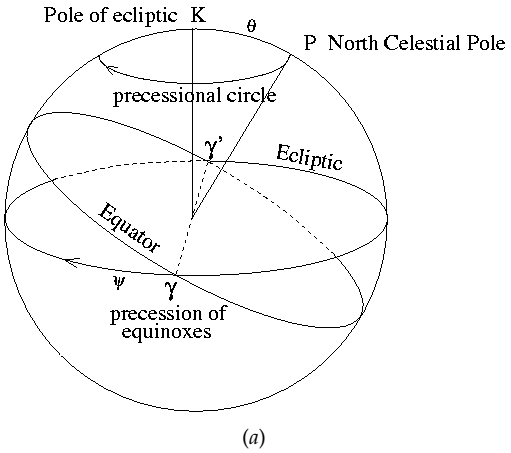
Precession

The first irregularity discovered in the Earth's rotation, and the largest one, does not concern the angular speed itself but the direction of the rotation axis with respect to the stars. In the Western world, as early as the 2nd century BC, the Greek astronomer HIPPARCHUS discovered that the vernal equinox, that is the direction of the Sun when it crosses over the equatorial plane towards the northern hemisphere, precesses with respect to the background stars. In other words, the equatorial plane turns clockwise at a fixed inclination of 23°26′ (obliquity) with respect to the ecliptic (figure 1(*a*)). The rate is of about 50″ yr^{-1} and thus the vernal equinox moves through all the constellations of the zodiac over the 25 800 yr precession period. At present the vernal equinox is in the constellation Pisces and is slowly approaching Aquarius, as shown in figure 1(*b*).

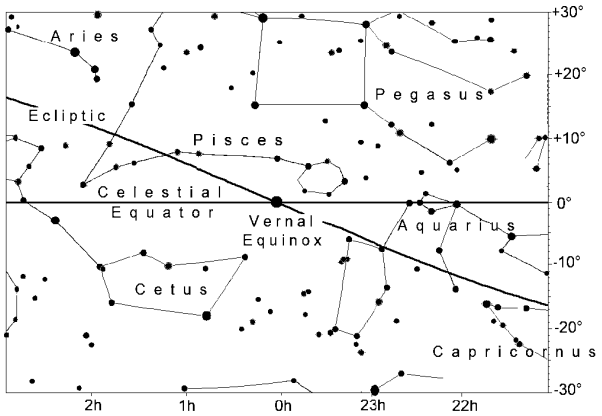
The diurnal rotation axis is perpendicular to the equatorial plane. Because of the PRECESSION, this axis describes clockwise a cone around the pole axes of the ecliptic, completing a turn in 25 800 yr, as shown in figure 1(*a*). At present the Earth's rotation axis points towards the Pole Star or North Star, but in 13 000 yr the precession of the rotation axis will mean that the bright star Vega in the constellation Lyra will be approximately at the North Celestial Pole, while in another 25 800 yr Polaris will once again be the Pole Star.

Nutation

Other irregularities in the Earth's rotation axis motion with respect to the stars are periodic oscillations of the rotation axis, called NUTATIONS, superimposed on the precession and predicted in the *Principia Mathematica* of Newton. These periodic oscillations are of much smaller amplitudes, no larger than 1′. Therefore they were not discovered until the advent of astrometric techniques at the beginning of the 18th century (see ASTROMETRY: HISTORY).



(*a*)



(*b*)

Figure 1. (*a*) Precession of the Earth's rotation axis (P) around the ecliptic pole (K). (*b*) Precession of the vernal equinox through the constellations.

In 1748, the English astronomer Bradley first observed the most important term of the nutation, associated with the regression of the lunar orbit's line of nodes, which has a period of 18.6 yr and an amplitude of the order of 10″. Other terms, up to several thousand in most accurate models, are at least 10 times smaller.

Polar motion

EULER predicted in 1765 that the rotation axis would also show a motion with respect to an Earth-fixed reference frame if the axis of rotation is not coincident with the principal axis of inertia—even if the Earth is isolated and a rigid body. The American astronomer Chandler took that important step with the discovery, in 1891, of that motion from observations of the geographical latitude of astronomical observatories. However, the main component is a 433 day periodic term, differing from that predicted by Euler (305 days) based on the Earth's ellipticity, because of the non-rigidity of the Earth. It has

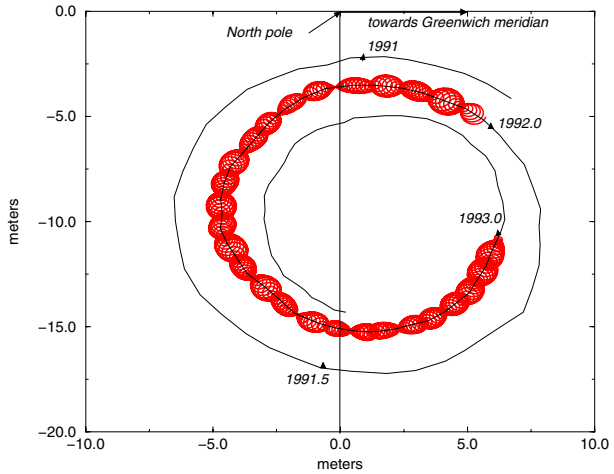

Figure 2. Motion of the Earth's rotation axis on the crust. Notice the long periodic polar motion composed of the annual term and the Chandler wobble, and the diurnal clockwise oscillations due to precession–nutation.

a variable amplitude up to 0.3″ (corresponding to 10 m on the surface of the Earth). As well as the Chandler wobble, an important annual term up to 0.1″ exists and is interpreted as the effect of seasonal mass displacements. Moreover, the precession–nutation gives rise to a small retrograde diurnal polar motion of the rotation axis in the Earth, as shown in figure 2 (see also POLAR MOTION AND LENGTH OF DAY).

Variations in length of day

Earth's diurnal rotation was humanity's time keeper until the discovery by de Sitter (1927) and Spencer Jones (1939) of the secular deceleration of the Earth's rotation speed and afterwards of its seasonal variations by Stoyko (1937) thanks to the improvement of precision clocks. Actually the rotation rate of the Earth's crust exhibits complicated fluctuations in speed to several parts in 10^{-8} (corresponding to a variation of a few milliseconds (ms) in the length of day, or LOD). These fluctuations are mostly seasonal (1 yr, half a year cycle) and also exhibit oscillations of all sorts of longer and shorter periods, such as the so-called 'decade fluctuations'. Moreover, analyses of solar eclipse observations recorded by Babylonians, Greeks, Arabs and Chinese indicate that the rotation rate decreases secularly, which causes an increase of the LOD of about 2 ms century^{-1}.

All these variations are the consequences of the angular momentum balance. This involves changes in the Earth's rotation due to the torques acting on the solid Earth as well as those due to changes in the mass distribution within the solid Earth, which modify its inertia tensor. This will be described in more detail in the section 'Dynamical description'.

Effect of the Earth's rotation on science and everyday life

As will be seen later, measuring the Earth's rotation involves nowadays large-scale, expensive observing techniques. Before we describe the state of the art, it is necessary to stress the importance of knowledge of the Earth's rotation by underlining its consequences in fundamental science, technology and everyday life.

The Earth's rotation and time

The Earth's rotation rules our whole life through the alternation of the days and nights. Therefore it constitutes the most natural unit for reckoning time. Inhabitants of the Earth are much more concerned about the diurnal cycle of the Sun than those of the star. From an Earth-bounded point of view, the Sun is moving slightly more slowly than a star, because the Sun is orbiting counterclockwise annually around the Earth whereas the diurnal sidereal rotation is clockwise. Hence the solar day is about 4 min longer than the sidereal day. Because of the variations of the Sun's velocity (or equivalently of the orbital velocity of the Earth in a heliocentric reference frame) and because of the OBLIQUITY OF THE ECLIPTIC, the solar day is subject to small variations of up to 30 s during the year. A mean solar day has been defined and conventionally taken as 86 400 s or 24 h. The diurnal cycle of the Sun constitutes the fundamental unit of the majority of calendars. Differences between CALENDARS concern the choice of greater cycle for reckoning the days (the month and the year), that is for establishing the dates. The Gregorian calendar, which constitutes nowadays the international reference, has been designed in order to keep the coincidence between the seasons and the occurrences of the equinoxes and solstices, of which the directions in space vary owing to the precession. As the tropical year is not a multiple of the number of days, the year of the Gregorian calendar contains an integer number of days but is subject to variations from one year to another (365 or 366 days), so that the mean year remains equal to the tropical year.

The succession of the mean solar days enables us to define a time scale, the so-called UNIVERSAL TIME. Thanks to the advent of the atomic clock, the Earth's rotation rate has been shown to be not uniform and consequently Universal Time has been given up as a time scale reference. The international time unit, the second of atomic time, has been chosen to be equal to the average of the second of the mean solar day for the epoch 1900. The INTERNATIONAL ATOMIC TIME scale, the Temps atomique international (TAI), is derived naturally with respect to the Universal Time (UT1) scale. In order to maintain the coherence between atomic time and universal time, an intermediary atomic time scale is maintained for civil use. This is the *Coordinated Universal Time* (UTC), which differs from the TAI by an integer number of seconds so that it never shifts from the UT1 by more than 0.9 s.

The Earth's rotation is crucial for physical theories

The Earth's rotation provides a validation of Newtonian dynamics. Newton asserts a distinction between inertial reference frames and non-inertial frames, undergoing acceleration with respect to the inertial frame, and in which the so-called non-inertial effects, such as centrifugal and Coriolis effects, appear. Assuming that a star-fixed reference frame is inertial, the rotating crust is a non-inertial frame. In turn the mass elements of the Earth should be subject to centrifugal effects, implying an equatorial bulge and a lower gravity at the equator than at the poles. This was shown in the 18th century by geodetic measurements and time pendulum recording at different latitudes and constituted a very important validation of Newtonian concepts. The second proof was obtained with the famous FOUCAULT'S PENDULUM designed by him in 1851, which exhibits an apparent turning of its oscillation plane under the Coriolis effect due to the Earth's rotation.

Geophysical effects of the Earth's rotation

The Earth's rotation strongly influences the atmosphere. First of all, the succession of the day and night induces daily fluctuations of temperature, and in turn changes of the pressure, and wind fields. Secondly the air motions are ruled partly by the Coriolis effect. This allows understanding of the wind patterns, especially the direction of the predominant winds with latitude.

The Earth's rotational irregularities have a role in geophysical phenomena. As an example, the decreasing rate of the Earth's rotation could induce a decrease of the Earth's flattening because of the decreasing centrifugal effect.

Geometric description—The Earth orientation parameters

The above considerations focus on the Earth's angular velocity vector. However, the astrometric or geodetic observations do not depend directly on this quantity but on the orientation of the ground-based stations and the celestial reference frame involved in the observations. Numerical methods, such as least-squares analyses, allow us to determine the orientation from the rough observations. In order to harmonize the determinations carried out around the world, the international scientific community has adopted a unique set of Earth orientation parameters (EOPs). The basic idea is to separate the modeled orientation changes from the unknown ones. The model provides the effect of mean diurnal rotation and of the precession–nutation. The difference between the real orientation and the model is described by five orientation parameters.

Firstly, two *celestial pole offsets* compensate for the defect in the precession–nutation model of the polar geographic axis; they are constrained by convention to contain oscillations having periods greater than a few days. The precession–nutation model and the celestial pole offsets define the spatial direction of an axis whose intersection with the celestial sphere is called the Celestial Ephemeris Pole. The word 'ephemeris' refers to the fact that the position of the pole in space is specified by the ephemeris provided by the conventional model for nutation.

The third parameter, the universal time variations $UT1 - UTC$, integrates the irregularities of the Earth's rotation speed. The Universal Time UT1 is the time scale built on the Earth's rotation angle, assuming that the rotation angle is proportional to UT1. As seen previously, the Coordinated Universal Time UTC is an atomic time scale, evolving uniformly with respect to the international atomic time (TAI).

Finally the two polar motion coordinates, x and y, provide the position of the Celestial Ephemeris Pole in the terrestrial frame, that is the shift between the Celestial Ephemeris Pole and the North Geographic Pole, but expressed in the terrestrial frame. It can be shown theoretically that the Celestial Ephemeris Pole represents as a first approximation the diurnal average of the Earth's rotation axis. Therefore the polar motion of the Celestial Ephemeris Pole, restricted to its long periodic variations, represents the motion of the rotation axis on the crust.

Actually three angles are sufficient to describe the defects in the *a priori* orientation of a terrestrial frame in a celestial frame. However, these angles include variations from several days or years (precession–nutation, long periodic polar motion) to 1 day and less. To estimate these parameters would require very intensive observations, which at present is not routinely achieved but will be soon as technology advances.

Monitoring the Earth's orientation

Evolution of the techniques

Astrometric and geodetic techniques provide the orientation as a function of time of the terrestrial frame with respect to the celestial frame from which the EOPs, including UT1, polar motion and precession and nutation quantities, can be derived. International services, successively since 1900 the *International Service of Latitude* (ILS), the *International Service of Polar Motion* (IPMS) and *the Bureau International de l'Heure* (BIH), have been in charge of collecting and combining the measurements in order to provide the best estimates of polar motion on a regular basis. The parameter UT1 was provided on a regular basis by the BIH from 1967. All measurements were based on optical observations done by Danjon astrolabe, or by transit, zenithal and circumzenithal instruments; they were provided for a 5 day interval, but the atmosphere limited their precision to 0.01″. Since 1972, several space geodetic techniques have been used for this purpose by BIH, beginning with satellite Doppler tracking and lunar laser ranging (LLR) and then, in 1978, satellite laser ranging (SLR) and very long baseline interferometry (VLBI) on extragalactic radiosources. Other satellites techniques, such as the Global Positioning System (GPS) and DORIS, have been considered in recent years. All these techniques provide time or frequency measurements. This is the primary information used by analysis centers for determining the EOPs.

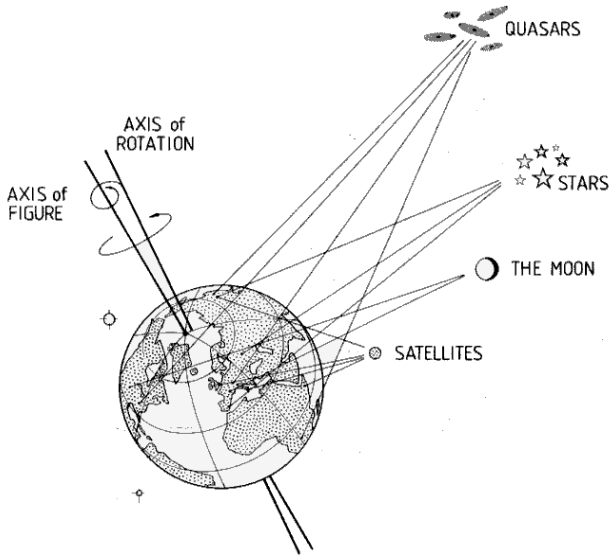

Figure 3. The techniques for observation of the Earth's rotation: the beacons are stars for astrometry, quasars for VLBI, satellites for SLR and GPS, Moon for LLR.

Today the astrometric methods have given way to the space geodetic techniques in routine Earth rotation measurements (see figure 3).

Since 1988, the international service in charge of the EOPs and the corresponding reference frames is the *International Earth Rotation Service* (IERS) whose *Central Bureau* is at Paris Observatory. The present accuracy is of the order of 0.2 mas (1 cm) for daily EOP determinations and can reach 0.5 mas for interval of the order of hours thanks to intensive VLBI or GPS sessions. This has led to a dramatic improvement in the determination of the EOPs and consequently of the knowledge of the details of the Earth's rotation and therefore of global geophysical parameters and geophysical processes influencing the Earth's rotation.

Modern geodetic techniques

In VLBI the basic quantity is the delay in wave front arrival at two radio telescopes from distant quasars. In the ideal case, this delay would be only a function of the orthogonal projection of the baseline between the two telescopes on the direction of the radiosource. The real case is more complicated because this delay contains non-geometrical effects, mainly due to clock synchronization and bending of the wave front in the atmosphere. Anyway, information on the Earth's orientation is contained in VLBI delays. Its modeling depends on many parameters which have to be estimated simultaneously. Until 1998 VLBI observation sessions have been carried out during 24 h at a few days' interval. They generally involved a set of baselines, observing consecutively several radiosources constituting the International Celestial Reference Frame. A distinction is established between arc parameters which are constant during the session (such as the coordinates of the radiosources, the EOP) and the local parameters (such as the clock parameters, the atmospheric delay) which differ from one session to another. Wave front arrivals are recorded on magnetic tapes independently at each radio telescope. All tapes are shipped to a central facility where they are cross-correlated to determine the series of differences in arrival time (the delay) and the rate of change of the delay (the delay rate) on the VLBI baselines (see figure 4).

Laser ranging techniques are currently used on satellites (satellite laser ranging or SLR) and the Moon (lunar laser ranging or LLR). This provides information on exactly how far the satellite is from the station at a particular time, which, in turn, can be used to determine the Earth's orientation in space. A very short laser pulse is transmitted from a telescope in a ground station, and it is retroreflected by a corner cube reflector on a satellite or the Moon back to the station. The round trip time is measured, which is equivalent to measuring the distance. It is now possible to accurately measure this up to 50 ps or better, which is equivalent to an accuracy of 1 cm or less.

GPS uses a constellation of satellites that broadcast signals to stations on the Earth. From the time delay of the broadcast signal and a precise determination of the satellites' orbits, the position of the station can be determined. A network of approximately 30 permanent stations is operated in order to help to establish a terrestrial reference frame. This network can be used to detect changes in the rotation rate of the Earth (the excess LOD) and in the orientation of its axis of rotation (the polar motion). High-frequency variations in the length of day are determined daily and are precise to $\pm 20\ \mu$s day^{-1}.

Comparison of the techniques

Table 1 provides a comparison of the performances techniques for monitoring the Earth's rotation. It turns out that the VLBI technique is the most efficient because the celestial reference frames realized by VLBI analyses are the most stable, and in turn the long periodic oscillations in the Earth's orientation, especially the precession–nutation and the several days' fluctuations in the LOD, are well determined. The international celestial reference frame itself consists of a set of radiosource coordinates provided by VLBI analyses. Satellite techniques do not provide such a stable reference frame. Because of many non-modeled effects in satellite orbits, the corresponding reference frame is only suitable for monitoring short-period terms of the Earth's orientation changes. Polar motion, which appears in a celestial reference frame as a quasi-diurnal counterclockwise oscillation of the geographic axis, is very well determined by satellite techniques, at the same accuracy level as VLBI.

The satellite techniques must be connected to an absolute UT1 value provided by an independent technique such as VLBI. This is necessary because a uniform rotation of the satellite orbit nodes cannot be distinguished from the Earth's rotation. However, because VLBI does not operate continuously, GPS can give better real-time LOD estimates to fill in the gaps.

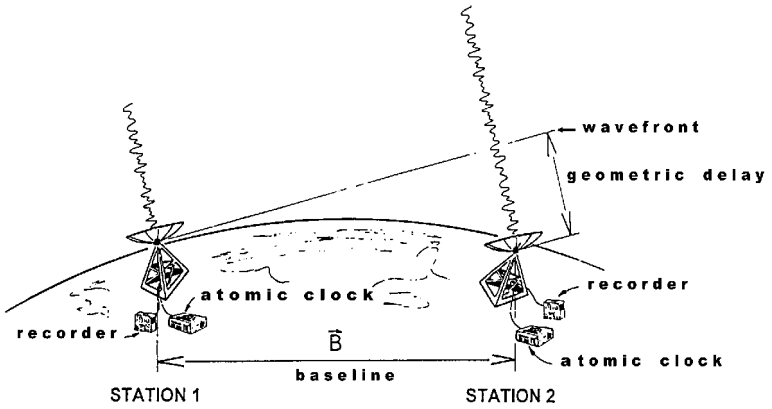

Figure 4. Observation of a quasar by VLBI.

Table 1. Potentialities of modern geodetic techniques according to the nature of the Earth's orientation parameters.

	VLBI	SLR	LLR	GPS
Precession–nutation	Up to 20 yr terms: 0.2 mas	Not currently applicable	Not currently applicable	Up to 13.6 day terms; VLBI necessary
Universal time	0.01 ms	0.02 ms	0.2 ms	0.02 ms; VLBI necessary
Polar motion	0.2 mas	0.2 mas	Not applicable	0.2 mas

Accuracy level of the determination is also reported. Unit for angles is milliarcsecond (mas), unit for UT1 is millisecond (ms).

Dynamical description

The dynamical causes of the Earth's orientation changes can be classified in two kinds: astronomical ones and geophysical ones. The astronomical causes, at our present state of knowledge, are reduced to the torque produced by the tidal gravitational attraction of celestial bodies on the Earth. The geophysical causes are associated with mass displacements in the Earth's layers (solid core, fluid core, mantle, oceans and atmosphere) or with interactions between the Earth's layers of an electromagnetic and a mechanical nature (gravitation, pressure and viscosity).

Let $\vec{H}$ be the Earth's angular momentum and $\vec{L}$ the external torque acting upon the Earth. In the geocentric quasi-inertial frame I (its axes, centered at the geocenter, do not rotate in space), the angular momentum balance is written as

$$\left(\frac{\mathrm{d}\vec{H}}{\mathrm{d}\vec{t}}\right)_I = \vec{L}. \qquad (1)$$

It is more convenient to consider a body-fixed frame **K**. Let $\vec{\omega}$ be the Earth's angular velocity vector; in **K** equation (1) provides the dynamic Euler equation:

$$\left(\frac{\mathrm{d}\vec{H}}{\mathrm{d}\vec{t}}\right)_K + \vec{\omega} \times \vec{H} = \vec{L}. \qquad (2)$$

The Earth's angular velocity vector consists of the constant diurnal rotation of the figure axis, that is the vector $(0, 0, \Omega)$ in the body-fixed system, and small perturbations $(\Omega m_1, \Omega m_2, \Omega m_3)$, m_1 and m_2 being for polar motion and m_3 for the relative variations in the Earth's rotation.

Solving equation (2) for a rigid body without any external torque results in a rotational eigenmode, the Eulerian wobble.

If one considers an elastic or inelastic body, we have to take into account the motion of each body element with respect to the system **K**. This causes variable increments of the moment of inertia c_{ij} and an additional angular momentum vector with components (h_1, h_2, h_3) in **K**. Expressing equation (2) as a function of the Earth's rotation vector, the Earth's inertia matrix, the additional angular momentum due to the non-rigidity of the Earth and the external torque and neglecting the cross-terms of the increments m_i, c_{ij}, h_i provides the so-called Liouville equations. The changes in the Earth's rotation and polar motion thus appear as the response of a differential system to a three-dimensional excitation vector. The excitation mechanisms result from a change in the Earth's angular momentum due to the application of an external torque, from a change in the Earth's inertia tensor and from internal redistribution of its angular momentum. Polar motion appears to be mainly excited by mass redistribution and LOD (i.e. m_3) by mass motions. Because of its linearity, such a system enables us to uncouple the sources of perturbations such as the effects of mass redistribution within the different parts of the Earth and the astronomical torque.

The classical way to solve the equations of the Earth's rotation involves two steps. Firstly the equations are solved for a rigid Earth model, only accounting for the astronomical forcing. Then one estimates to what extent this 'rigid solution' is modified by introducing the non-rigid structure of the Earth and geophysical effects such as air mass displacements. These two steps are described in more detail in the following.

Astronomical forcing

The Moon and to a lesser degree the Sun exert a gravitational tidal torque on Earth's equatorial bulge. The Moon contributes more than twice as much as the Sun owing to its proximity, which compensates for its smaller mass. This torque, lying in the equatorial plane, exhibits in an inertial system spectral components ranging from half a day to several thousand years, according to the periodic variations in the orbital elements, causing in turn variations in the direction of the geographic polar axis and rotation axis. These variations are classically described by two Euler angles, a *precession angle* ψ in the ecliptic plane and an inclination *angle* θ or obliquity, giving the offset between the Earth's axis (geographic or rotation axis) and the axis of the ecliptic poles (see figure 1(*a*)).

In the case of a rigid Earth model the problem of the precession–nutation is reduced to a purely astronomical problem. Solving the Liouville equations, we obtain the rigid Earth's angular velocity vector $(\omega_i^{\text{rigid}})_{i=1,2,3}$ as a function of the external torque and of the dynamical flattening of the Earth. By integration of kinematical relations linking the component of the angular velocity vector to the time derivative of the EOPs, the Euler angles of the geographic axes with respect to the axes of the quasi-inertial frame can be derived. They provide the variations in ecliptic longitude ψ and obliquity θ.

The quasi-stationary torque component, that is the term turning clockwise with sidereal period for a terrestrial observer, induces secular variations of the Euler angles. The most important concerns the angle ψ and amounts to $50.29''\ \text{yr}^{-1}$. This is the so-called *astronomical precession*. In turn the rotation axis describes, as a first approximation, a cone around the axis of the ecliptic poles in 25 800 yr. The periodic variations of the tidal torque, ruled by the motion of the Sun and the Moon in a geocentric reference frame, induce periodic variations in the rotation axis direction, the so-called *astronomical nutation*. At equal torque amplitudes the effect is more important for greater periods. Indeed the longer is the period the longer is the duration during which the periodic variation can take place. Mathematically the Euler angles results from the torque integration and hence from the division of any spectral component by its frequency. This explains why the biggest nutation terms are not necessarily induced by the largest torque components. As an example, the largest nutation term, in 18.6 yr, is a quasi-circular term of amplitude about $10''$, which is more than 200 times the amplitude of the term in 13.6 days, induced by the strongest tidal component. Moreover, because of the planetary perturbations on the Earth's orbit (i.e. the ecliptic), the obliquity is decreasing at a rate of $0.46''\ \text{yr}^{-1}$ (i.e. the axis of rotation is less and less tilted).

In the case of a rigid Earth model, the angular velocity is constant except for very small variations of diurnal and semidiurnal periods and amplitudes up to 2×10^{-6} s in UT1, due to the effect of the non-zero component of the luni-solar tidal torque in the equatorial plane.

Geophysical effects

The case of a real Earth is more complicated than considered in the previous section.

First, there are deformations under the influence of tidal gravitational forcing and centrifugal forcing which induce moment of inertia changes. The inertia changes of tidal origin are responsible for a modification of the amplitudes of nutations as well as for the zonal variations of the Earth's rotation at the same periods as the nutations and amplitudes up to 1 ms in UT1, both effects being scaled by the elasticity factor (Love number k) of the mantle. The elastic deformations of centrifugal origin are responsible for the major part of the modification of the Chandler period as compared with the Euler period.

Second, the fluid core and the mantle do not rotate rigidly; the fluid core naturally has a clockwise nearly diurnal wobble with respect to the crust, because its main inertia axis does not coincide with the mantle inertia axis and this causes by reaction a similar effect on the mantle. The period of this rotational free motion, also referred to as the free core nutation, is strongly dependent on the flattening of the core–mantle boundary and has been shown to influence the near-resonance tidal amplitudes. In a celestial frame, the free core nutation would appear as a clockwise oscillation. Theory predicts resulting perturbations of clockwise nutations of a rigid Earth, as confirmed by VLBI observations. Solving for the rotation of a non-rigid Earth model thus requires us to write Liouville equations for the mantle and the core separately and to solve both these equations simultaneously. Finally the angular velocity vector of the mantle $(\omega_i)_{i=1,2,3}$, induced by the external forcing, is expressed as a function of the rigid solution $(\omega_i^{\text{rigid}})_{i=1,2,3}$. Present models of precession–nutation, taking into account the rigid solution and non-rigid effects such as the presence of a fluid core inside the Earth with a flattening that deviates from hydrostatic equilibrium, agree with observations at the submilliarcsecond level. The value of the dynamical flattening of the Earth, which is a fundamental parameter of the models, is derived from the observed precession rate.

In addition, we have to consider the displacement of masses inside the Earth's superficial layer. These geophysical processes influence the Earth's rotation as much as the Moon and the Sun, but their energy is mostly released in the long periodic range (several days) with respect to the crust, in contrast to the gravitational influence which is daily retrograde. Most of them are independent of the Earth's rotational perturbation;

they are triggered by thermal, tidal and electromagnetic influences. However, the variation of the centrifugal forces associated with the wobble of the rotation axis induces a change of the water height in the oceans, called the 'pole tide'. This phenomenon plays a fundamental role in accounting for the period of the Chandler wobble.

The changes of air and oceanic mass distribution involve variations of the Earth's rotational speed as well as a long periodic displacement of the rotation axis with respect to the crust. Annual components up to 2 ms in the LOD and up to 200 mas in pole motion are induced by the atmospheric circulation. The observed subseasonal components (10–100 days) can be explained by the combined effect of the atmosphere and the oceans. The most common approach for computing the effects of the fluid layers is based on the angular momentum time series of these layers (quantities c_{ij} and h_i) and the Liouville equations. Meteorological centers provide us with atmospheric angular momentum (AAM) series from pressure and winds assimilation models. The oceanic data are much less common, so that the oceanic angular momentum results mostly from modeling. The correlation between LOD and AAM is so well established that forecasts of atmospheric angular momentum provided by the major centers are now being investigated for prediction of the Earth's rotation.

Some geophysical forcing of larger periods (more than several years) can be expected from the observations. This might involve the superficial layers (for instance the El Niño cycle in the atmosphere and in the ocean) and the coupling between the core and the mantle. Such mechanisms can explain the decade-long fluctuations of the LOD. The major contribution to secular change in the LOD is attributed to tidal friction which transfers Earth's spin angular momentum to the lunar orbit, the complementary contribution originating from the effect of the post-glacial rebound on the Earth's principal moment of inertia.

The observed secular motion of the pole with respect to the crust, called the 'secular pole trend', of about 0.3″ century^{-1} in the direction about 70°W is mostly attributed to mass redistributions accompanying and following the termination of the Pleistocene glaciation 20 000 yr ago. Other geophysical causes are also under consideration such as a global rise in sea level or trends in groundwater storage and recent glacial activity.

It can be considered that variations in the Earth's rotation (precession, nutation, polar motion and LOD) are now quite well explained by the various geophysical effects described above (mass redistributions, influence of the fluid core, forcing of the atmosphere and the oceans, etc), except for a very puzzling component, the Chandler motion of the pole. As seen above, this component has the period of a free rotational mode of the Earth, about 433 days. The theory shows that, in the absence of any external torque, the rotation axis turns around the figure axis in the terrestrial frame with this period. As the Earth is not a perfect elastic body, this motion should be dissipated in thermal energy. However, no damping of the Chandler motion has been observed. Consequently it is excited by some mechanism, which is not yet elucidated. Neither the combined effect of the atmosphere and the oceans nor earthquakes seem to give the appropriate forcing.

Recent progress

Diurnal and subdiurnal determination of the polar motion and universal time

Vast progress in astrometric and geodetic observing techniques has taken place in the last few decades, as seen below. The progress is not only restricted to the increasing accuracy of the EOPs. Since the 1990s the intensification of geodetic observations by VLBI and GPS has enabled the determination of subdaily variations of the polar motion and the Earth's rotation speed. Since 1999 VLBI observations have been done continuously and more intensively by different antenna networks working alternatively. New phenomena have been put forward, which are diurnal and semidiurnal changes in the polar motion and in the Earth's rotation speed. These variations are mostly explained by the oceanic tides. Other components of non-tidal origin might be detected, but no firm statement can be made yet.

Free core nutation

Furthermore, the modeling of Earth's orientation changes has been improved. Until the 1980s the conventional precession–nutation model was that of a rigid Earth. However, the non-rigidity effects are up to 100 mas, which are 1000 times the accuracy of the VLBI observational results. Since 1980 much interest has thus been focused on the refinement of the nutation model by taking into account the deformation of the mantle as well as the interaction processes between the fluid core and the mantle. The parameters of such a model are of primary geophysical interest, such as the flattening of the fluid core. Models constrained by VLBI observation allow one to deduce these parameters. From the observed period of the free core nutation (430 days), it has been found that the fluid core has a flattening greater than that associated with a hydrostatic equilibrium, corresponding to a 500 m increase of its equatorial radius. Observation of geophysical processes, such as earthquakes, does not enable such a fundamental result to be obtained.

Future

New discoveries of Earth's rotational irregularities can be expected from the increasing performance of modern geodetic techniques. Nevertheless, these techniques rely on very costly processings. The ring laser gyro based on the Sagnac effect and frequently used in navigation systems constitutes an interesting alternative, because it does not need any astrometric observations and allows one to do astronomy *in situ*. With this technique, still in development for monitoring the Earth's rotation, oscillations at a time scale lower than 1 h could be detected.

Earth's Rotation: Theory

The Earth's rotation theory is devoted to explaining the variations of the Earth's rotation. Additionally to the uniform rotation around an axis close to the geographic North pole, the Earth undergoes variations in rotation speed (including changes in the length of the day); furthermore, the orientation of the rotation axis changes with time, inside the Earth as well as with respect to inertial space. In a terrestrial frame, the motion of the rotation axis around the mean geographic pole is called polar motion; in the celestial frame, the motion of the rotation axis in space is called PRECESSION/NUTATION.

Variation of the Earth's rotation rate, variation of the length of day

The variation of the length of day (LOD), as measured by geodetic observations over recent decades, is at the level of several milliseconds for periods shorter than a few years (see the article on the EARTH'S ROTATION). These short-term variations are mainly induced by atmospheric and oceanic effects on the Earth. They can be computed from models constrained by meteorological data by considering (1) that the atmospheric pressure (or indirectly the ocean pressure) pushes on the Earth's topography (e.g. on the mountains) thereby producing a torque which changes the Earth's rotation, (2) that the density variations in the atmosphere give an additional torque (gravitational torque), and (3) that the winds also induce a friction torque on the Earth's surface. Similar torques are also introduced by the ocean. Altogether these phenomena induce acceleration and deceleration of the Earth's rotation at short time scales and, in turn, associated variations in the LOD. The Earth's variation of the LOD can be computed and compared with the ANGULAR MOMENTUM of the EARTH'S ATMOSPHERE, as done in figure 1.

Besides these variations, there are decade variations of the LOD (see above and the remaining differences in figure 1 between the measured LOD variations and those computed from the atmosphere) which are usually attributed to an exchange of angular momentum with the core because of the correlation between the surface magnetic field variations and the variations of the LOD at these time scales. This angular momentum transfer is due to torques at the CORE–MANTLE boundary (CMB): (1) a topographic torque, due to the pressure of the fluxes acting on the CMB topography (bumps and valleys which can be as high as a few kilometers); (2) a viscous torque, related to the viscosity of the liquid core; (3) an electromagnetic torque, related to the Lorentz force induced at the CMB by the electromagnetic field; (4) a gravitational torque, related to the gravitational interaction between the core and the mantle of the Earth. The topographic torque and the electromagnetic torque are usually believed to be the most important ones at long time scales. Also, the gravitational torque has attracted a lot of attention recently. Because there are no direct observations of the core flows to lead to well-constrained models such as exist for the ocean and atmosphere, only indirect calculations of the core angular momentum (and thereby of the torque acting on the CMB) can be obtained. Their variations can be calculated, if the motions in the core are characterized by rotation of fluid cylinders, from the flows at the top of the core derived from variations in the poloidal magnetic field observed at the surface. Further, these flows depend on poorly constrained additional assumptions to resolve formal non-uniqueness in the solution. Consequently, it is very speculative to give the associated changes of the Earth's angular momentum or the torques acting on the inner core–outer core boundary (ICB) or CMB, without any other constraint. Nevertheless, the Earth's rotation variations being well correlated with the magnetic field at decade time scale, data of variations of the LOD can be used to constrain the core angular momentum and the torques at decade time scale.

There is also a very long-term trend in the variation of the LOD as observed from paleontological data (coral growth in time) and from eclipse data (lag between the date deduced from a uniform rotation and the date given in past records); this very long-term trend is related to the deceleration of the Earth's rotation induced by tidal friction. Due to friction, the tidal bulge created by the classical tidal torque has a phase angle of about 5 degrees with respect to the Earth–Moon position. Because of this, the Moon exerts an additional torque which tends to break the Earth's rotation. This induces a linear trend in the solar time corresponding to an LOD increase of about two milliseconds over one century (this would almost not be seen on figures showing time-dependent functions over 14 years as presented here). This tidal friction is the reason why in the Devonian period, for instance, there were only 22 hours in a day.

Besides the tidal torque which is the predominant mechanism in reducing the Earth's spin, there is another long-term component acting to decrease the LOD (by about half a millisecond per century) and related to the decrease of the Earth's oblateness associated with deglaciation after the ice ages.

Polar motion

The polar motion in recent times is within a 20 m size square at the Earth's surface around the North pole (see POLAR MOTION AND LENGTH OF DAY). There are two main components: (1) one which has an annual period and is believed to be due to the atmosphere, but might well be additionally caused by other seasonal phenomena such as groundwater changes, and (2) another which has a period of about 435 days and is related to a normal mode of the Earth called the Chandler Wobble (CW). The CW is related to the fact that the Earth has an equatorial bulge inducing an excess of mass at the equator with respect to the pole (the Earth is oblate and has an equatorial radius larger than the polar radius by 21 km). The excitation of the CW is not well established but is generally believed to be mainly due to the atmosphere.

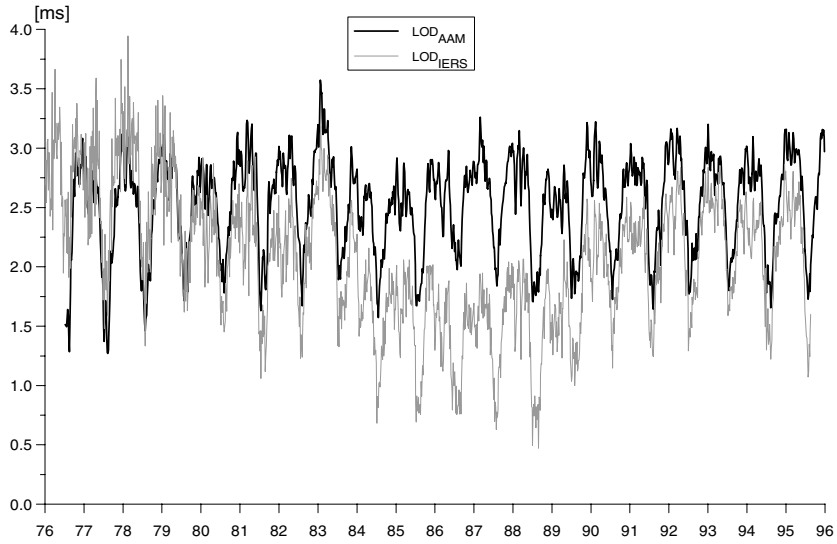

Figure 1. Comparison of the atmospheric angular momentum and the variations of the LOD for the last 14 years.

Additionally to these two periods there is a long-term trend called polar wander which is explained by internal-mass redistributions over long periods such as that associated with post-glacial rebound and mantle convection.

Precession/nutation

The luni-solar attraction on the Earth's equatorial bulge induces a torque which tends to rock the equator toward the ecliptic. The Earth responds to this as a gyroscope; its rotation axis undergoes a large motion around the perpendicular to the ecliptic of about 50 arcseconds per year. The opening of the associated cone is the angle between the equator and the ecliptic (23° 26′). The relative positions of the Moon, the Earth and the Sun being not fixed in space, in addition to this precessional motion, there exist periodic motions of which the periods are directly related to the periods involved in the relative positions of Moon, Earth and Sun: the nutations. The largest nutation amplitude corresponds to the period of the node of the Moon's orbit around the Earth (18.6 years) on the ecliptic. Figure 2 shows schematically the precession and nutations.

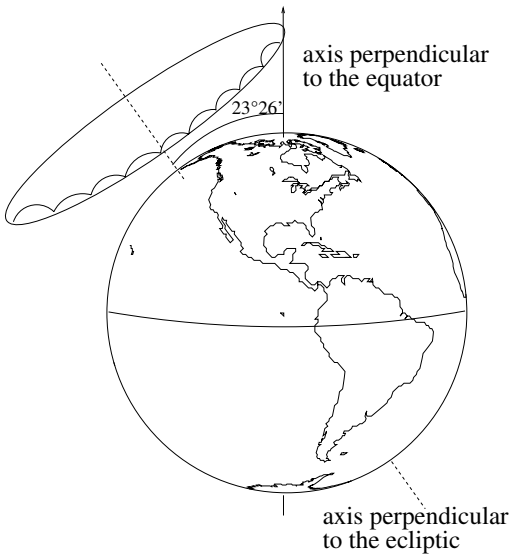

Figure 2. Schematic representation of precession and nutations.

There are actually very precise models to compute the Earth's orientation in space (for space navigation for instance). These models are based, on one hand, on computation of the Earth's nutation for a rigid body and, on the other hand, on the transfer function for a non-rigid Earth.

The rigid Earth nutation series are computed from CELESTIAL MECHANICS starting from EPHEMERIDES which give the relative positions of the Earth, Moon, and Sun (and to a minor extent the relative positions of the planets) as a function of the time variation of the fundamental argument (e.g. the longitude of the Moon). Present-day theories have an accuracy at a few microarcsecond (μas) level (1 μas $= 10^{-3}$ mas, and 1 mas is the angle with which one would see a ping-pong ball on the top of the Empire State building in New York from Europe). This accuracy is better than the nutation observation accuracy. These theories do not only include the nutations related to the direct gravitational interaction between the Moon and the Earth, and between the Earth and the Sun, but also all the second-order effects such as the perturbation of the Sun on the Earth–Moon interaction, the perturbation of the Moon on the Earth–Sun interaction, the direct and indirect effects of the planets, the effect of the presence of the equatorial bulge of the Earth (J_2-tilt effect) and the effects of the nutations on each other (coupling effect).

The accuracy of non-rigid Earth nutation transfer

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

functions is currently not as good as for the rigid Earth nutation series. The models used generally consider that there is (1) an inelastic, solid, deformable inner core, (2) a liquid outer core, and (3) an inelastic, deformable mantle. They take into account the non-hydrostatic equilibrium state of the Earth which is very close to the hydrostatic ellipsoid, but not exactly, because of the presence of mass heterogeneities inside the Earth (as seen from seismic mantle tomography or from the non-ellipsoidal contributions to the geoid). The global Earth dynamical flattening of the models corresponds to the observed value (derived from the observed precession), and the CMB topography accounts for the non-hydrostatic bumps related to the deformations induced by mantle convection. The nutations computed from the convolutions between the rigid Earth nutation series and the transfer function are influenced by resonances with free modes of the Earth, especially the free core nutation (FCN) which has a period of about 432 days in the celestial reference frame. The computed normal mode periods are very close to the observed values, particularly due to the consideration of non-hydrostatic equilibrium. Some very recent models account additionally for electromagnetic coupling at the CMB. These models are precise at the sub-milliarcsecond ($<$ mas) level.

Additionally to these computations of nutations in response to the luni-solar (and planetary) gravitational attractions, the atmosphere has a non-negligible influence at the VLBI observation precision level. The atmosphere exerts a pressure torque, a gravitational torque and a friction torque on the Earth at diurnal time scale in a frame tied to the Earth. The friction torque is believed to have a negligible contribution to nutation. The atmospheric one-solar-day effect on the Earth induces a perturbation on the prograde annual nutation at a level of a tenth of a mas. Similarly, the diurnal ocean tides induce perturbation in the principal nutations. The indirect effect of the ocean due to the atmospheric forcing must also be taken into account. The atmospheric and oceanic torques cause an angular momentum transfer, and consequently, the effects on nutations can also be computed from the angular momentum balance equation, instead of calculating the torques. The so-obtained perturbation of the nutation is at the level of the tenth of a mas for the atmosphere effects, and of a mas for the ocean tide effects.

Earthshine

A faint illumination of the Moon's night side by sunlight reflected from the Earth. It is visible when the Moon shows a crescent phase, as a pale grayish ghostly glow over the remainder of the disk. Earthshine is traditionally known as 'the old moon in the new moon's arms'; seldom-used alternative names are *earthlight* and the *ashen light*. Earthshine is difficult to see less than a day after new moon because the Moon is then very low in a twilit sky. It is most noticeable about two days before or after new moon. At three or four days from new moon the illuminated portion of the disk is large enough to begin to swamp the pale earthshine. A lesser factor affecting the strength of visible earthshine is the phase of the Earth as would be seen from the Moon. At new moon the Earth is full, and reflects the most sunlight toward the Moon. Three or four days from full, the Earth would be gibbous and not nearly as bright. The intensity of earthshine also varies from one lunation to another, mainly as a result of changing levels of cloud cover over the hemisphere of the Earth presented to the Moon.

Eckert, Wallace John (1902–71)

Computer scientist and astronomer. Born in Pittsburgh, PA, Eckert was a pioneer of the use of IBM punched card equipment for astronomical calculations. As director of the US Nautical Almanac Office he introduced computer methods to calculate and print tables instead of relying on human 'computers'. When, later, he became director of the Watson Scientific Computing Laboratory at Columbia University he directed the construction of computers, tailor-made to calculate the positions of the planets and Moon. It is hard to imagine the world of astronomy today without the computers and methods that he pioneered.

Eclipse

An eclipse of the Sun is an OCCULTATION at which the Moon comes between the Earth and the Sun, blocking some or all of the sunlight from reaching an observer. Eclipses result from the fortuitous circumstance that the angular sizes of the Sun and the Moon as seen from Earth are the same to within about 10%, although in absolute diameter they differ by a factor of 400.

Types of solar eclipses

Solar eclipses can be total, annular or partial. At a total eclipse, the cone of lunar shadow is intercepted by the Earth's surface. The intersection traces out a path that instantaneously is close to an ellipse but that over a period of hours traces out a path thousands of km long but only up to about 300 km wide. Observers in this umbra, from which the solar photosphere is entirely blocked, see a total eclipse, while observers in a much larger area ahead or behind or to the sides of the umbra are in the penumbra and see a partial eclipse. Only during the total phase of a total solar eclipse does the CORONA become visible, and so it is mainly these total eclipses that are scientifically valuable. Totality can last from fleeting instants up to about 7 min (figure 1).

Because of the ellipticities of the orbits of the Moon around the Earth and the Earth around the Sun, mainly the former, the conical shadow of the Moon sometimes does not reach the Earth's surface. At those times, observers on Earth see an annulus of photosphere surrounding the Moon, and the eclipse is said to be an annular eclipse. Since the photosphere is approximately a million times brighter than the full Moon, an annular eclipse with 10% or even only 1% of the photosphere showing allows so much sunlight to hit the Earth's atmosphere that the sky remains blue and the corona is not visible. Annularity can last as long as 12 min.

Total and annular eclipses are known as central eclipses. Occasionally, less than 10% of the time, the umbra reaches the earth for only part of a central eclipse, and an annular–total solar eclipse occurs. Sometimes the conical umbra of the Moon's shadow is directed beyond the Earth's poles, and no total or annular eclipse occurs on Earth. These eclipses are partial only.

Although the mean semidiameters of the Sun and the Moon are 960" and 931" respectively, the ellipticities of 0.055 and 0.017 for the Moon around the Earth and the Earth around the Sun, respectively, provide enough range in apparent sizes to account for annular and total eclipses. The Moon can appear as much as 10% smaller than the Sun or 8% larger.

The umbra, if it were to hit the Earth vertically, could not exceed about 270 km in diameter, but the projection onto the globe can almost double this figure.

Frequencies of solar eclipses

The 20th century contained 224 solar eclipses, including 147 central eclipses and 77 partial eclipses. There are between two and five solar eclipses in any given year, although only about every 18 months is there a total eclipse visible somewhere on Earth. An observer waiting at one location on Earth would see a total solar eclipse on average only once every 375 years, a rate that depends on latitude. However, observers willing to travel can observe

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

eclipses much more often. Even for a single country, statistics over a 3000 yr interval (Williams 1996) show that total eclipses are visible in England on average every 44 yr. Over the same interval, eclipses are visible at London every 330 yr and at Edinburgh every 186 yr. The paths of the total eclipses of 21 June 2001 and 4 December 2002 cross at the west coast of southern Africa, giving a region there two total eclipses within 18 months.

The umbral shadow moves across the Earth at about 3400 km h^{-1}. Earth's rotation allows surface points to diminish this relative velocity. The maximum rotation speed is about 1700 km h^{-1} for a point at the equator, so the relative velocity of the umbra diminishes for a time to about 1700 km h^{-1}, a speed at which the supersonic Concorde once kept up with the 1973 eclipse for 74 min. Normal jets, however, extend totality only slightly. Orbiting satellites would travel through the umbra with an even greater mismatch of speeds, so natural eclipses are not observed from space.

Predicting eclipses

Eclipses are predicted with a method descended from that worked out by F Bessel in 1824. Eight Besselian elements are given in a frame of reference of the Moon's shadow, as explained by Espenak (1987) and in the *Explanatory Supplement to the American Ephemeris* (1992). The Besselian elements of an eclipse are related to a fundamental plane that is perpendicular to the Moon's shadow and that passes through the center of the Earth. The coordinates x, y and z are then oriented east, north and parallel to the axis of the lunar shadow, respectively. The Besselian elements are then x and y for the shadow, the radii of the penumbra and umbra on the fundamental plane, L_1 and L_2 respectively, the direction of the shadow's axis on the celestial sphere, given by declination and hour angle d and μ respectively, and the angles with which the penumbra and umbra, respectively, intersect the axis, f_1 and f_2. These Besselian elements are tabulated or can be calculated by a variety of computer programs.

F Espenak and J Anderson, for each total eclipse, produce a NASA Reference Publication with tables and maps, taking over a function that was formerly covered by US Naval Observatory Circulars. See http://umbra.nascom.nasa.gov/eclipse/. Programs are now available for even the amateur market that accurately predict eclipse paths. The CD-ROM *RedShift* is an example. The *Scientific Astronomer* package for *Mathematica* includes eclipse-prediction capabilities.

Details of the calculations use a constant k for the fractional mean radius of the Moon–Earth, and this constant has been empirically adjusted to account for the observed average size of the Moon and Sun. Whether an eclipse is total depends, after all, on the complete coverage of the Sun by the lunar disk, while a phenomenon known as Baily's beads result from the last bits of solar photosphere shining through the deepest valleys on the lunar limb. So depending on assumptions, different calculations result in slightly different numbers for the frequency of total eclipses. The IAU value (1982) is $k = 0.272\ 507\ 6$, but a smaller value of $k = 0.272\ 281$ is better used for computing totality. Calculations taking lunar librations into account must be made for individual eclipses.

A solar eclipse is but an especially well-aligned new moon. The planes of the orbits of the Moon around the Earth and the Earth around the Moon are inclined by 5º. They intersect at only two points, known as the ascending node and the descending node. Only when both the Sun and the Moon are close to a node simultaneously can an eclipse occur. Because the Moon cannot move out of a node in a half-month interval, there is always a lunar eclipse 2 weeks before or after a solar eclipse, although most of these eclipses are not total. These eclipse seasons are separated by 173.3 days, giving an eclipse year of 346.6 days. In years that have three eclipse seasons, a total of five solar eclipses can occur, a circumstance that will not occur until 2206.

The saros

A coincidence in the cycles of the Sun and the Moon results in a repeat of eclipses with approximately the same characteristics every 18 yr $11\frac{1}{3}$ days, a period named the 'SAROS' by Edmond Halley. The period may have been discovered by the Babylonians.

The coincidence is several, including the following: (a) 223 synodic months = 6585.32 days, where a synodic month is the period of the lunar phases; 242 nodical months = 6585.36 days, where a nodical month (also called a draconic month, after the mythical Chinese dragon who supposedly devoured the Sun at eclipses) is the interval at which the Moon passes successive nodes in its orbit; 239 anomalistic months = 6585.54 days, where an anomalistic month is the period over which the Earth–Moon distance varies; 19 eclipse years = 6585.78 days, where an eclipse year is twice the interval between successive eclipse seasons, the 38 day period during which the Sun and Moon are sufficiently near the nodes that eclipses can occur.

The coincidence of 223 synodic months = 242 nodical months means that an eclipse occurs $6585\frac{1}{3}$ days = 18 yr $11\frac{1}{3}$ days after a previous eclipse. (Depending on how leap years fall, the interval can be 18 yr $10\frac{1}{3}$ days or 18 yr $12\frac{1}{3}$ days.) The 1/3 day means that the path of the successive eclipse is 1/3 of the way around the globe with respect to the earlier one. The further coincidence of the anomalistic month means that total eclipses are followed by total eclipses and, in addition, that long ones are followed by long ones after the saros interval, and so on. For example, the saros series that includes the longest eclipses (with maximum durations of totality in

parentheses) includes 30 June 1973 (7 min 4 s), 11 July 1991 (6 min 53 s), 22 July 2009 (6 min 39 s), 2 August 2027 (6 min 22 sec) and so on. Throughout this saros, the Moon's diameter is 8% larger than the Sun's. Successive eclipses drift in latitude, and the duration of the saros series now active range from 1244 yr to 1514 yr.

Historical eclipses

Records of eclipses can be found on cuneiform tablets from ancient Babylonia and on records from China, giving thousands of years of data. The earliest surviving Babylonian record is the eclipse of 731 BC. Shang dynasty Chinese sources range from ca 1350 BC, although reliable records date only to about 700 BC. Stephenson (1997) has analysed a range of such ancient eclipses to determine the rotation rate of the Earth, since whether an eclipse is total or not at a given point depends on this rate. Ancient documents can often be analysed to see whether the eclipse was total, since the difference between total eclipses and other solar eclipses is so dramatic. Stephenson continues his study through medieval European records and Arab chronicles, to provide a graph of the length of the day over time based on over 400 eclipse observations. He finds a difference in ΔT, the difference between mean solar time and ephemeris time, of approximately 20 000 s over a range of over 2700 yr. Much of the change in the rotation rate of the Earth derives from lunar and solar tides, but he also finds non-tidal contributions, perhaps resulting from post-glacial uplift affecting the terrestrial oblateness. A day was approximately 42 ms shorter in 500 BC than it is now, although the graph shows a periodic term in addition to a trend.

Stephenson discusses in detail each of the ancient reports and assesses its reliability. For example, many of the supposed eclipse reports allow of alternative interpretations. Perhaps the most famous ancient eclipse is the one of 28 May 585 BC, which Herodotus (died ca 425 BC) related (as reported by Pliny in the 1st century AD) was predicted by Thales of Miletus and stopped a war between the Medes and the Lydians. Stephenson's conclusion, however, is that Herodotus has exaggerated and that the eclipse was not actually predictable at that time. Stephenson states that 'the first person to give the true explanation of eclipses was Anaxagoras (500–428 BC),' but quotes Neugebauer as concluding that eclipses were not predictable for hundreds of years after that.

Eclipse phenomena

Eclipse calculations specify the times of the contacts. First contact is the first meeting of the disks of the Moon and Sun; it is noticeable to an observer looking through a filter with unaided eye within a few seconds. Second contact is the complete coverage of the solar photosphere by the Moon; it marks the beginning of totality. Third contact is the first appearance of the solar photosphere after totality; it marks the end of totality. Fourth contact marks the departure of the lunar disk from the photosphere. It is little observed, since observers often lose interest after the excitement of totality.

The interval between first and fourth contact is commonly 3 h and can be as long as 4 h. For most of the time between first and second contacts, the eclipse would not be noticeable to anyone who did not know that it was occurring. However, for the last 15 min or so before second contact, the sky color noticeably changes and shadows grow strangely sharper, since they are now being cast by a crescent instead of a sphere. During the last couple of minutes before totality, shadow bands, low-contrast ripples of light and dark, are often seen to move rapidly across the landscape. They are very difficult to photograph and are better observed photoelectrically. Since they are caused by phenomena in the Earth's upper atmosphere, they are of little interest to solar physicists, but atmospheric physicists might similarly be more interested in them than in the solar phenomena that are soon to become visible.

As the crescent narrows, within the last minute before second contact it begins to break up into individual beads, known as Baily's beads. They are named after the English astronomer Francis Baily, who noted them at the eclipse of 1836, though they had earlier been commented on. Depending on the sky quality, the solar corona may or may not be visible during this period. The last Baily's bead glows so brightly compared with the other solar phenomena visible—the chromosphere and/or the innermost corona—that it looks like the diamond on a ring and is known as the diamond-ring effect. It often lasts only a few seconds but can last nearly a minute, depending on the depth of the deepest valley on the edge of the Moon that is aligned properly to transmit photospheric light. The glitter of a diamond is often matched in images by internal scattering in camera lenses. (See figure 2).

As the diamond diminishes, a pinkish narrow rim on the Sun becomes visible. It got the name 'chromosphere' from its colorful appearance at eclipses. Depending on how much larger in angular size the Moon is than the Sun, you may be able to see the full chromosphere at one time or you might see only the leading edge at second contact and then the trailing edge at third contact. The pink color comes largely from Hα, and has an admixture of other chromospheric emission lines. Spectra taken over this interval show the photospheric absorption lines fading and chromospheric emission lines flashing into view (that is, appearing abruptly), the flash spectrum.

As the diamond ring and chromosphere disappear, you have totality (figure 3). The shape of the corona becomes visible, with CORONAL STREAMERS obvious. The shape of the corona varies over the solar-activity cycle. At solar minimum, most of the streamers visible

are equatorial, and polar tufts show near the poles. Isophotes of the corona appear elongated. At solar maximum, streamers are visible at more latitudes and isophotes of the corona appear nearly round.

SOLAR PROMINENCES have become visible during the diamond-ring effect and chromosphere period, and if sufficiently large may remain visible throughout totality.

All too soon, within a period no longer than about 7 min 30 sec and often much less, a brightening region of the corona becomes visible as the Moon progresses across the Sun, the pinkish chromosphere becomes visible again and a second diamond ring appears to mark the end of totality. The rest of the eclipse phenomena, including Baily's beads and final crescents and later partial phases, proceed in reverse order from the ingress.

Eclipse safety

The brightness of the solar corona during totality is approximately that of the full moon, and the corona during totality is equally safe to watch. However, staring at the crescent or other partial phases of the eclipse can be hazardous to eyesight, so warnings should be given to the populace about how to watch an eclipse safely (see SUN: SAFE OBSERVATION). All too often, the distinction between the hazards of the partial phases and the safe glory of totality is lost or not understood by reporters or by the public. One often runs across a popular belief that some special rays are emitted by the Sun during an eclipse that make it unsafe to watch or even to be outdoors. This belief is totally untrue, of course; there is less of everything during an eclipse, including less solar radiation.

Next, we discuss viewing methods for the partial phases of an eclipse; it is important to note that the filters described are only for the partial or annular phases and must be removed to view totality.

On a normal day, one is not tempted to stare at the Sun, and the eye-blink reflex normally prevents you from doing so. However, during the partial phase of an eclipse, people's interest has been called to the Sun, and during the crescent phases the total intensity of sunlight may be inadequate to activate the eye-blink reflex even though the specific intensity of regions of the solar photosphere that is still visible remains high. Thus people should observe the Sun only through special filters. These filters cut out all but about 1/100 000 of the photospheric light, reducing the photosphere to a safe level for observation.

The key factor in safe solar filters, aside from their absorbing or reflecting sufficient levels of solar intensity, is that they do so evenly across the spectrum—that is, they are of neutral density (ND). With each level of density given logarithmically, filters that pass only 1/100 000 the light are ND5. Solar filters made of aluminized Mylar, a coated plastic, are very popular and are available inexpensively. As long as these Mylar filters are undamaged, without creases or pinholes, they are safe to look through. Unfortunately, they are now often distributed in the form of eyeglasses, which may tempt people to stare at the Sun through them, rather than as simple rectangles to hold up and look through. Although the solar intensity seen through them has been reduced to a safe level, it is still a good extra safety precaution never to stare at the Sun.

For telescopic use, filters made of chromium deposited on glass pass the requisite amount of photospheric light to photograph and view the partial phases while giving images of excellent definition. A

very slight increase in transmission at the red end of the spectrum often gives a pleasing tint to the solar image. Welders' glass of #14 or #15 is also safe for visual or photographic viewing, although the color is usually less pleasing. Photographic 'ND filters', such as Wratten filters, are not safe for use at eclipses, since they are transparent in the infrared rather than being ND across the spectrum. Similarly, crossed polarizers are also unsafe.

A very safe way to view the partial phases is with a pinhole camera. Such a device is no more than a small hole, perhaps 2 mm–5 mm across, in a piece of cardboard or aluminum foil (perhaps taped in place over a larger hole in cardboard). This small hole is held 0.5 m–1 m or so above a piece of paper or cardboard, and one looks down at this second surface with the Sun over one's back. The shape of the partial phase is visible on this second surface and is completely safe to look at. The interstices among the leaves of a tree often act as their own natural pinholes, and the ground or other surfaces under trees often show multiple pinhole images of the partial eclipse and its progression.

An analogous method using an optical device is 'eyepiece projection', where an eyepiece is cranked beyond its normal focal point and used to project an image of the partially eclipsed Sun on a paper, cardboard or other screen. One looks only down at the screen, never up through the telescope.

Though the eye is not damaged by occasional unaided glances at the Sun, which often occur accidentally on normal days, it can be immediately and permanently damaged by the focused image of the Sun through a telescope or binocular. So if a telescope or binocular is used in a direct-view mode, a solar filter must be taped or otherwise secured very carefully to the front of the optical device so that it cannot blow off or fall off. Filters that go on the eyepiece end are always liable to crack or be otherwise damaged under the concentrated solar radiation, so are much less safe than filters above the objective lens. Viewing through a properly filtered telescope or using eyepiece projection has the advantage over pinhole cameras of showing sunspots, which do not normally show in pinhole images.

Many people have heard of viewing the partial phases through smoked glass, achieved by holding glass in a flame. This method is undesirable because of the unevenness of the coating and the ease in its being damaged. A later traditional method is to use two or three layers of fogged and developed black-and-white film. As long as the film contains silver, which not all of the new black-and-white films do, and it is completely exposed to light and then is developed to full density, it should be safe for use, since the silver provides ND. Color film and slides are transparent in the infrared and must not be used as filters. Fogged and developed x-ray film works well, but one must be careful not to be misinterpreted when giving instructions, because I have heard of someone using regular x-rays and looking through the light parts that show the bones. Similarly, some compact disks (CDs) work as solar filters, if they are coated sufficiently densely, but novices should be warned not to look through the hole.

All too often, the need for instructions on how to observe safely is misinterpreted by school officials or by the press to mean that people should be warned not to look at the eclipse directly. Since so much of the glory of watching the eclipse comes from the rapid changes in ambient light and from the extreme contrasts of the eclipse phenomena themselves, much of that effect is lost in watching an eclipse on television. Stories of students being prevented from watching eclipses by school personnel abound and are most unfortunate since students can be inspired by observing such natural phenomena. Further, when teachers exaggerate the hazards when telling students about eclipses, students can soon learn the true situation and regret having missed seeing the phenomenon. Then they will lose trust in the teachers and may not take their advice on other matters, including health-related ones like taking drugs or smoking.

The occasion of an eclipse is an excellent one for public information about science. It is important to give accurate information early on to the general public and to students. It is further important to distinguish between the partial (or annular) and total phases of an eclipse. Since the corona is approximately 1/1 000 000 the brightness of the photosphere, even if 99% of the photosphere is hidden, the remaining 1% is still 10 000 times brighter than the corona. So the general public should be informed that a so-called 99% eclipse is very far from totality, and that to see the exciting eclipse phenomena they must journey to the zone of totality.

Eclipse science

One of the main advantages of solar eclipses is that the solar corona can be observed with the latest instruments and with cognizance of the latest theoretical ideas. Thus the types of discoveries that have been and can be made at eclipses changes over time.

Since only a few minutes at most of totality are available at eclipses, it is usually desirable to extend or continue observations at a forthcoming eclipse. Further, new ideas about the solar atmosphere may suggest new observations to be made. In addition, eclipses sample the solar-activity cycle, with different prominences and coronal features visible at each.

Eclipse expeditions began in the 18th century and reached maturity during the 19th. The first coronal photograph was taken in Koenigsberg in 1851. Prominences were discovered to be intrinsic to the Sun rather than artifacts during the 1860 expedition to Spain. The diamond ring effect was first photographed at the 1859 expedition, and photographs at the 1870 and 1871

expeditions were used to prove that the corona was intrinsic to the Sun by comparing photographs from widely separated locations.

Perhaps the most famous eclipse discovery was made at the 1868 eclipse in India. A spectrograph revealed the brightest emission lines of the CHROMOSPHERE for the first time. At first a bright yellow line was thought to be the D line of sodium, but it was soon realized that it was displaced from the D_1–D_2 sodium doublet, and was called D_3. D_3 was so bright that it was realized both from the eclipse results and independently elsewhere that it could be viewed outside of eclipse. The element that caused the D_3 line in the spectrum was called 'helium', from the Sun god Helios, since it was known to exist only in the Sun. Helium was not identified on Earth until 1895. The flash spectrum was discovered at the eclipse of 1870, when it was thought to reveal a 'reversing layer'.

Starting with the total eclipse of 1869, additional emission lines were discovered that came from the corona, and were said to come from 'coronium'. The periodic table had not been completed at that time, so it was not obvious that 'coronium' was any less an element than 'helium'. In slitless spectra, in which the brightness of the chromospheric and/or corona itself is used to define the part of the image that is to be dispersed, the chromospheric emission lines appear as arcs while the coronal lines appear as circles. The brightest coronal lines in the visible part of the spectrum, all that could then be studied, are the 'green line' at 530.3 nm and the 'red line' at 637.4 nm. A dozen fainter coronal lines have also been identified in the visible. The source of these spectral lines was not identified until 1939 and following years, when they were shown to be from 13-times-ionized iron ([Fe XIV], where the neutral state is Fe I and the square brackets indicate that the lines are forbidden by the quantum-mechanical selection rules) and from nine-times-ionized iron ([Fe X]), respectively. This result was the proof, backing other lines of evidence that had not been generally accepted, that the corona is very hot, containing gas at millions of kelvins.

The observations by Eddington and colleagues at the 1919 eclipse expeditions that stars very near the Sun were deflected slightly, as predicted by Albert Einstein in his general theory of relativity, led to the acceptance of Einstein's theory. The Sun was in the Hyades during the eclipse, giving an especially rich star background. Eclipse observations for the purpose of testing relativity have been repeated several times since, and the old data from 1919 and 1922 have been reanalysed, but there are better methods of now of verifying the same principles and this Einstein experiment is no longer a major part of eclipse research.

Rocket missions are sometimes flown during eclipses. The Lyman-alpha corona was discovered during a rocket flight that took slitless spectra during the 1970 eclipse. The Lyman-alpha image was not expected because of the high temperature of the corona, but even at millions of kelvins sufficient hydrogen remains un-ionized to scatter enough photospheric light to be observed. This Lyman-alpha corona is now observed from telescopes on the space shuttle and on satellites. Other eclipse rockets are flown at the same time as eclipses but out of totality, for comparison with eclipse results. High-resolution x-ray images are obtained for this purpose, for example.

The corona observed at eclipse comes from several different sources. The K-corona (from the German word *Kontinuierlich*) is caused by photospheric light scattering off coronal electrons. In the scattering process, Doppler effects broaden the photospheric absorption spectrum to oblivion, or nearly so, and polarize the light. The F-corona (from Fraunhofer) is the light from the photosphere that scatters off dust in interplanetary space. Although dust is vaporized very close to the Sun, by the orbit of Mercury there is sufficient dust to make an important contribution to the corona as viewed from Earth. This scattering preserves the Fraunhofer absorption spectrum and does not polarize the light, so spectra and polarization measurements are commonly used to 'separate' the F- and K-coronas. The emission lines of highly ionized species, like the coronal green and red lines, are measurable only very close to the solar disk, just above the lunar disk at eclipses. The relative contributions of these different parts of the corona are shown in figure 4. The dust itself can be measured in the infrared, and is sometimes called the T-corona (from thermal). The F-corona is the inner part of the zodiacal light.

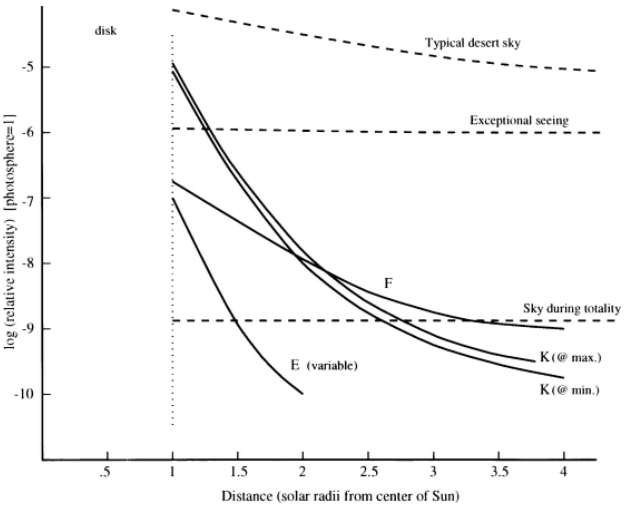

Figure 4. The intensities of different parts of the corona. K is the continuous (spectrum) corona, F is the Fraunhofer (absorption line) corona and E is the set of emission lines. (From Golub L and Pasachoff J M 1997 *The Solar Corona* (Cambridge: Cambridge University Press); after van der Hulst H C 1953 *The Sun* ed G Kuiper (Chicago, IL: University of Chicago Press).

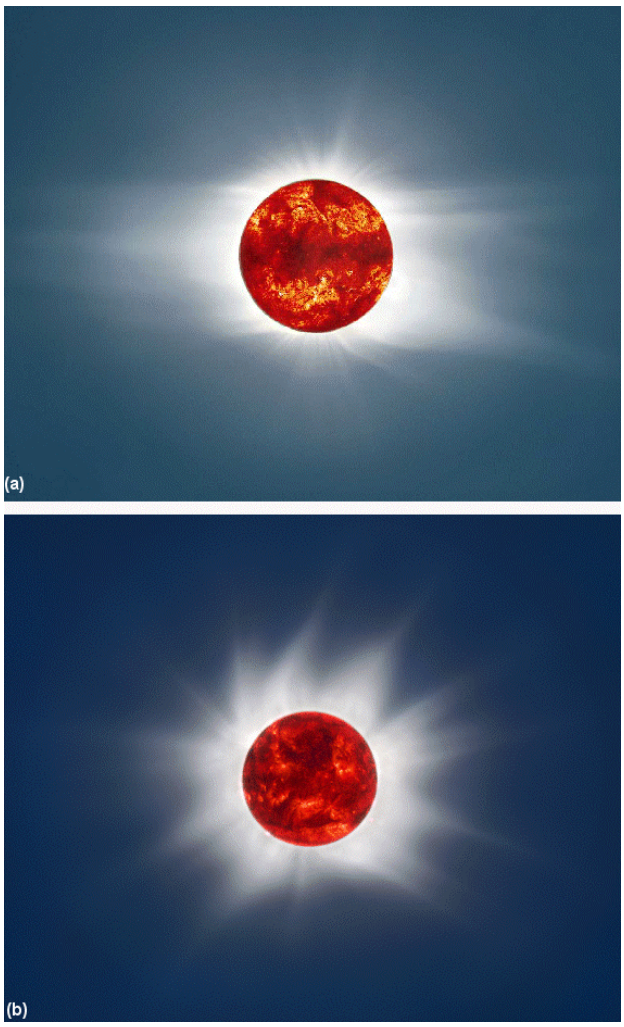

Figure 5. (*a*) The total solar eclipse of 26 February 1998, with an image of the solar disk based on observations from the Extreme-ultraviolet Imaging Telescope (EIT) on the Solar and Heliospheric Observatory (SOHO). The EIT central image shows the coronal temperature, and was computed as the ratio of two of their individual images that show the corona in different temperature ranges. © 1999 Jay M. Pasachoff and Wendy Carlos. All rights reserved. Central image from the EIT/SOHO team, NASA Goddard Space Flight Center. SOHO–Williams College collaboration with the support of the Committee for Research and Exploration of the National Geographic Society.

(*b*) Composite image from August 11 total solar eclipse with SOHO EIT image of the solar disk superimposed on coronal features photographed by the Williams College Eclipse Expedition. SOHO EIT images courtesy of the EIT team at NASA Goddard Space Flight Center, combined by Wendy Carlos.

Since the corona diminishes in intensity so rapidly with distance from the solar limb, a factor of about 1000 in the innermost solar radius above the limb, ordinary film or CCDs cannot capture the intensity of the whole corona on a single image. Accordingly, G Newkirk worked out a method in the 1960s, following earlier work by Laffineur and others, of making an eclipse camera with an ND filter that is radially graded in density so that it is densest near the limb and progressively less dense radially outward. Thus the coronal image that passes the filter is flatter in intensity than the original image, and can be captured on a single piece of film. Ten such images were taken, from 1966 through 1998. Radial filters have also been used by other observers. At present, computer techniques are allowing similar effects to be created using multiple images taken with varying exposure times, as was shown in figures 1 and 4. Such images show the shapes of coronal streamers especially well and thus reveal the SOLAR MAGNETIC FIELD.

Although the innermost corona has been observable from certain mountaintop observatories since the coronagraph was invented by Lyot in the 1930s, those observations were limited to regions closer to the limb than were visible at eclipses. The K-coronameter now at Mauna Loa Observatory and some other coronagraphs can now be used to observe the corona farther out, but are still limited in coronal observability. The brightness of the daytime sky, even at high altitude from such coronal sites as Mauna Loa or Haleakala, remains too high to carry out the full range of coronal studies.

With solar satellites aloft viewing the corona every day, we have entered a new era in coronal eclipse research. There are still niches for which the Sun can be better studied from the ground than at an eclipse, and scientific work at eclipses must be pointed to those studies. For example, the spatial region within the limit of the occulting disk of the innermost coronagraph of SOHO can be observed at an eclipse. Cadences can be achieved at eclipses that are quicker than those available from SOHO, Yohkoh, or TRACE, which has the potential of solving the problem of CORONAL HEATING MECHANISMS. Further, regions of overlap can be analysed to the mutual benefit of eclipse and space researchers. For example, space instruments can be calibrated by comparison with eclipse results, or the forbidden lines visible from the ground can be compared with the permitted lines of the same ionic species observed from space. Eclipse coronal observations can extend the LASCO coronagraph observations into the solar limb, within LASCO's 1.8 solar radius occulting disk (and even the 1.1 solar radius disk of a defunct component). The comparison of ground-based eclipse observations with space results can extend the value of either type of observation (figure 5).

Table 1. Total solar eclipses, 2000–2010.

Date	Maximum duration	Path of totality
21 June 2001	4 m 57 s	Southern Africa (Angola, Zambia, Zimbabwe, Mozambique, Madagascar)
4 December 2002	2 m 4 s	Southern Africa (Angola, Zambia, Botswana, Zimbabwe, South Africa, Mozambique), Pacific Ocean, ending at Western Australia
23 November 2003	1 m 57 s	Antarctica
8 April 2005	0 m 42 s	Total only at maximum over the Pacific Ocean
29 March 2006	4 m 7 s	West (Ghana, Togo, Benin, Nigeria, Niger, Chad, Libya, Egypt), Turkey, Russia, top of Caspian Sea, Kazakhstan
1 August 2008	4 m 27 s	Northern Canada, Greenland, Russia (Siberia), western Mongolia, China
22 July 2009	6 m 39 s	India, Bangladesh, northernmost Myanmar, China
11 July 2010	5 m 20 s	Pacific Ocean, ending over southern Chile and Argentina

Future eclipses

Total eclipses occur about every 18 months (figure 6(*a*)), table 1 and annular eclipses occur with about the same frequency (figure 6(*b*)). The partial phases are visible for thousands of kilometers to the sides of the zones of totality or annularity.

Eclipsing Binary Stars

We have an eclipsing binary when the stars of an orbiting pair periodically pass in front of one another, thereby dimming light from the system. Bright eclipsing stars such as Algol and ϵ Aur excite the interest of even casual observers, and many are within reach of binoculars. Both stars are eclipsed in most examples, although usually one of the alternating eclipses is much more prominent than the other, and eclipses of only one star are possible. The existence of eclipsing binaries is expected when one realizes that many stars occur in binaries[1], although whether they are common or rare is a matter for further thought and observation. Historically, the discovery of eclipsing binaries was one of the first indications of binary nature. (See VARIABLE STARS for early history and BINARY STARS: OVERVIEW.) Although initial mental images may be of simple spherical stars, a host of interactive phenomena includes tides, winds, impacting streams, magnetic starspots and transfer of energy, while results provide checks, insights, and discoveries for the fields of stellar structure and evolution. Classes are named after prototypes, such as the abundant RS CVn, Algol and W UMa binaries. Typically a class originates with its recognition in terms of common observational traits, followed by several false starts toward understanding. The class may reach mature status, as have the mentioned classes, when there is widespread agreement on its coherence and on the structure and evolution of its members—of course with surprises at all stages. The central thread that has led from classification to structure and evolution is the idea of limiting lobes and the natural morphological types built around them. Thus we have detached (see BINARY STARS: DETACHED), semidetached, overcontact and double-contact binaries—somewhat pictorial names with formal meanings that are developed below. The eclipsing binary concept has grown to include eclipses of and by circumstellar disks, eclipses of fluorescent circumstellar gas by one or both stars and eclipses of the stars by attenuating clouds of circumstellar material (see DUSTY CIRCUMSTELLAR DISKS). The best-known eclipsing binary results are accurate fundamental data on masses, luminosities and radii of stars (MLR data), while classical problems concern the origin, structure, evolution and general nature of binaries, with impact on our understanding of star clusters and galaxies.

Information from eclipsing binaries

Eclipsing binaries have primarily been discovered by photographic surveys, with a few turned up by accident in photoelectric work. They can be found at great distances and many are known in other galaxies, although limiting magnitudes and spatial resolution set practical limits. Larger light loss (eclipse depth) leads to greater likelihood of discovery and usually to greater astrophysical usefulness. The orbit is edge on to the observer for an inclination, i, of 90° and high $\sin i$ obviously favors deep eclipses, as does a large ratio of star size to orbit size. *Total eclipses* (entire star covered) and *annular eclipses* (only a ring of surface not eclipsed) are favored by unequal star sizes and, of course, by high $\sin i$. A *complete eclipse* is one that is either total or annular, while a *partial eclipse* is neither total nor annular. The deepest eclipses occur when a star with most of the system luminosity (in a given photometric bandpass) is totally eclipsed, as in RW Tau. Annular eclipses, partial eclipses and eclipses of stars with low relative luminosity are typically much less deep and may even be undetectable. Total eclipses detectable only in x-rays can occur when a normal star has a hot neutron star companion. For circular orbits, the star with higher average surface brightness over the eclipsed area, which ordinarily means the star of higher surface temperature, necessarily has the deeper eclipse. The situation is more complicated for an eccentric orbit binary where one eclipse may be near periastron and rather deep, with the other near apastron and quite shallow or absent. Decrease of $\sin i$ reduces eclipse durations and depths, but only slightly for inclinations near 90°. Larger reductions occur when $\sin i$ becomes too low for complete eclipses.

Brightness is measured relative to a judiciously chosen constant comparison star, nearby on the sky, while Doppler shifts are relative to the spectrum of a stationary light source. Velocity curves for both stars are ordinarily required for full results on absolute dimensions. The roles of light and velocity curves can be envisioned via a motorized scale model with glowing stars. Place the model in the sky (surmounting practical difficulties) at a distance of a few kilometers and observe its light curve, which could be indistinguishable from that of a real binary. By applying knowledge of eclipses and other photometric effects we might find relative dimensions, but nothing in the light curve tells us the model's tiny absolute dimensions. Radial velocity curves deal with real lengths and can testify to the model's absolute size but will not provide a picture. We therefore need both light and velocity curves to derive both image information, including relative dimensions, and the absolute scale.

Among phenomena that make light curves informative are tidal and rotational distortions, mutual heating, gravity brightening, limb darkening, magnetic star spots and accretion hot spots. Brightness variations due to tides and heating are collectively known as proximity effects. They tend to be prominent in eclipsing light curves because the same characteristic that makes eclipses likely also enhances tides and heating. Statistically, that characteristic is *large star size relative to orbital separation*, although tidal distortion is more directly dependent on star size relative to limiting lobe size. Prior to about 1970 proximity effects were mainly regarded as hindrances to eclipse analysis, while spots were not widely seen as real. With an evolution in thinking, all these effects are now recognized as valuable indicators of physical and geometrical binary star properties.

[1] Estimates range from somewhat over half to 90+% of stellar systems being binary or multiple.

Ellipsoidal variation is named for the approximately ellipsoidal figure of a tidally distorted star. It is periodic on the orbit period, being concave-downward between conjunctions and concave-upward around the conjunctions (figure 1). That is, tidally distorted stars appear brightest from the side and dimmest end on. In the rather extreme case of overcontact, the overall binary system is shaped somewhat like a dumbbell as in figure 1. The term *ellipticity effect* also is used, particularly when a distinction is made between variation due to shape (*geometric ellipticity*) and to the consequent surface brightness distribution (*photometric ellipticity*). Photometric ellipticity arises because of gravity brightening, where local surface flux depends on effective gravity. Theory predicts that bolometric flux is proportional to effective gravity in the case of radiative energy transfer and roughly to the 0.3 power of gravity for convective transfer. The first prediction is from the theory of RADIATIVE TRANSFER, while the second comes from numerical models of convective stellar envelopes. The geometric and photometric brightness variations have roughly equal amplitudes (radiative case), with similar waveforms, and add to a total variation almost twice that from geometry alone (figure 1). In the convective case, total variation is only moderately greater than the pure geometric effect. Ellipsoidal variation is largest for overcontact binaries with strong tides and radiative envelopes such as TU Mus, where it can reach amplitudes of order 30% of mean system light. Amplitudes are quite noticeably smaller, although still important, for the very abundant W UMa type overcontact binaries with deep convective envelopes. Many binaries have sin i too low for eclipses but still show ellipsoidal variation, as does the bright star Spica, which thereby varies about 3%. Ellipsoidal variation also can 'hide' from observation by affecting only the dim member, as in ALGOL where the lower mass star has a very large tide but only 2% of the luminosity of its nearly spherical companion. The gravity effect not only brightens a system as seen from the side, but also reduces the inward-facing brightness of each star relative to its outward-facing side, so that it appears dimmer at superior than at inferior conjunction. Ellipsoidal amplitudes tend to be small for eccentric orbits because the stars are only briefly near periastron, where tides are strongest. Ellipsoidal waveforms become more complicated with increased orbital eccentricity because tides are then variable and at best quasi-static. A likely example of aperiodic dynamical tides is GP Vel, the site of x-ray source Vela X1.

Radiative heating of each star by the other produces the *reflection effect*. Thermal re-emission from a reflection cap on the inward side causes a light curve elevation around superior conjunction as part of a periodic variation that can be described by a few Fourier terms. Note that this difference at the conjunctions is opposite in sign from the corresponding one for ellipticity. The typical overall result of the two reflection effects seen together is a hill around secondary eclipse (figure 2) and intereclipse variation that is concave-upward. (The upward concavity is very subtle and usually is overpowered by any small ellipsoidal variation.) The enhancement near secondary eclipse arises from the separate reflection effects being a half-cycle out of phase and the cooler star having the larger effect. One might expect local energy conservation in incident versus re-emitted radiation, but theory and observation indicate that irradiated stars with deep convective envelopes conserve energy only globally and re-emit about half of incident energy locally. Thus the *bolometric albedo* parameter, (locally re-emitted energy)/(incident energy), is unity for radiative envelopes but only about 0.5 for convective envelopes, which have reduced reflection amplitudes.

Limb darkening is a wavelength-dependent aspect phenomenon caused by the temperature gradient in a stellar atmosphere and made familiar by observations of the Sun. It alters eclipse shapes and depths in ways that are mainly subtle but can be obvious in annular eclipses. Light curves of RS CVn type, BY Dra type and some other categories show variable 'maculation' waves caused by heavily spotted areas (figure 3). In some binaries these magnetic starspots drift in longitude and their maculation waves accordingly migrate steadily in phase, perhaps superposed with ordinary ellipsoidal and reflection variation.

While each light curve effect has something to tell, eclipses deserve their top billing, as even minimal eclipses greatly delimit possible configurations. That fact becomes apparent when one tries to understand a binary with several kinds of variation but no eclipses. Multibandpass observations are particularly useful when the star temperatures differ greatly, as short and long wavelengths respectively emphasize contributions from the hotter and cooler stars. Parameters derivable from eclipses are listed in table 1, with comments. Among these, P, e, ω, M_2/M_1 and a reference time are also derivable from radial velocities in suitable circumstances, while i appears in the velocity parameters $a_{1,2}$ sin i. Thus an i from light curves allows extraction of a_1 or a_2 from single-lined velocities, or both from double-lined velocities, and thus contributes to establishing the absolute scale and absolute masses.

There is much active research on unusual and bizarre binaries where information retrieval can be difficult but well worth the trouble, as it can point to new directions in stellar evolution. Quasi-periodic and irregular variations call attention to interesting characteristics and evolutionary histories. For example, RS CVn binaries were first noticed because of light curve waves due to magnetic starspots, but the evolutionary significance of RS CVns now runs far beyond that phenomenon. However, quite regular timewise behavior sometimes stimulates a flood of research when its implications are appreciated. The stars of a W UMa binary exchange thermal energy through a connecting neck, yet are remarkably stable and long lived. The issue of why they are stable has generated a large literature over many decades, so observationally

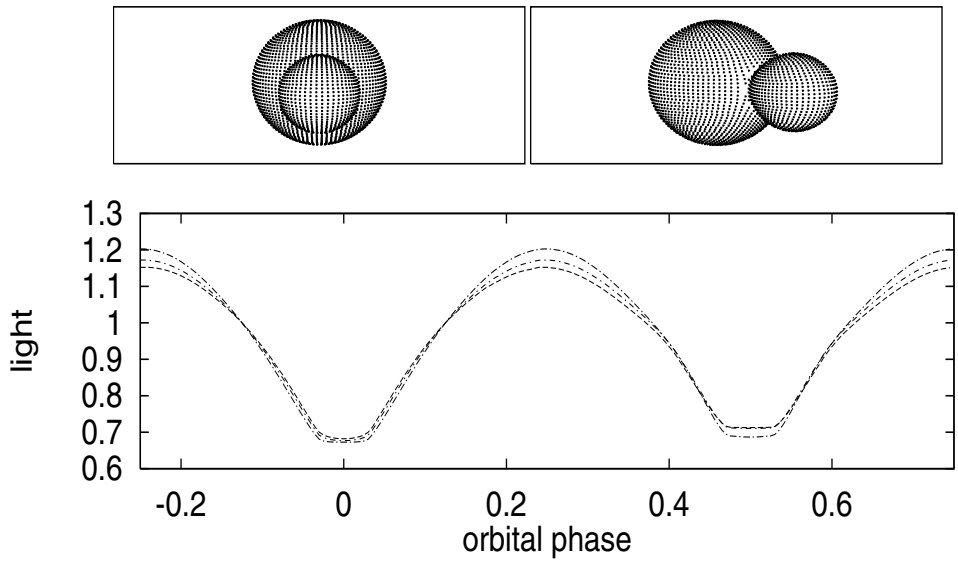

Figure 1. The effect of gravity brightening on the ellipsoidal variation of a tidally distorted binary is shown by the three curves in the lower panel. The largest amplitude is for the full effect, as expected for radiative energy transfer. The smallest amplitude shows the purely geometrical part of ellipsoidal variation. The in-between amplitude is for the reduced gravity brightening expected for convective energy transfer. The top panels are computer simulations of the binary at two places in its orbit.

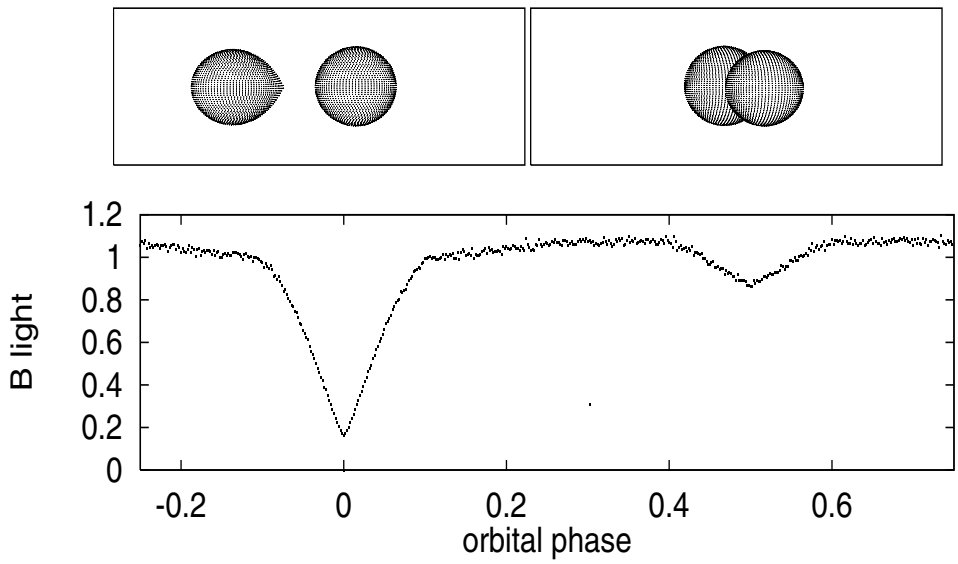

Figure 2. The reflection effect is seen in this simulated blue light curve of Z Vulpeculae (lower panel). Notice the hill around secondary eclipse as the heated inward-facing side of the lower-temperature star turns toward the observer. The low-temperature star is the one with the large tide, as shown in the computer pictures of the top panels. It is nearly the same size as its hot companion, but far less massive and therefore much more distorted.

simple binaries can be theoretically intricate. Nature makes many contenders for the title of strangest binary, but β Lyr and ϵ Aur have continued as leading candidates for most of a century. Subsets of their observations look deceptively simple, but straightforward interpretations lead quickly to contradictions. Binaries that break the rules make us re-examine our assumptions. Light curves also differ in intricacy, apart from whether the behavior is understood. Certain red giants with small hot companions (SYMBIOTIC STARS, especially symbiotic novae) show eclipses of fluorescent stellar winds and chromospheres that exhibit great detail, especially in spectroscopy and multiwavelength photometry. Although the fundamental phenomenon seems to be understood, much is being

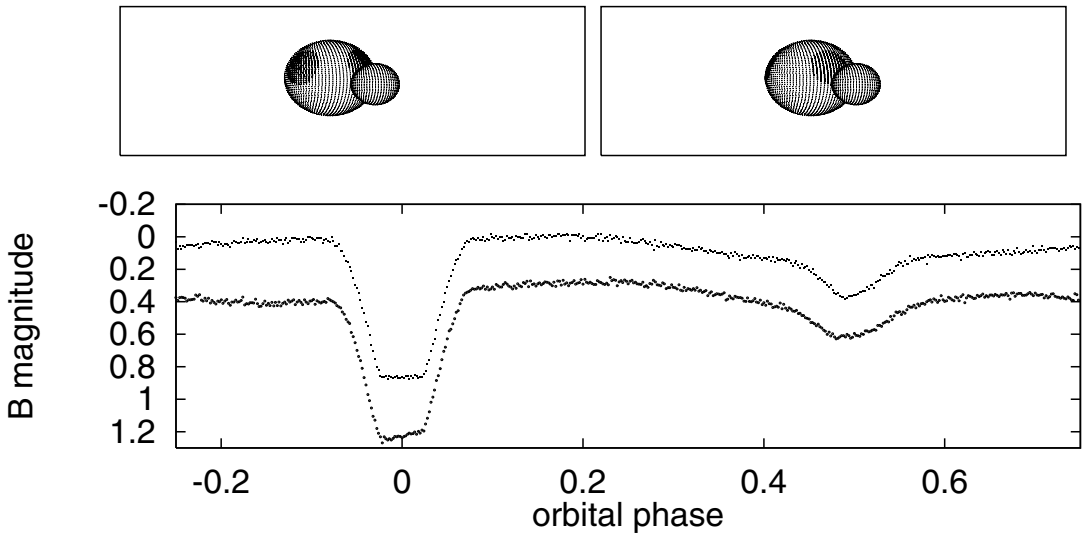

Figure 3. Here the RS CVn type binary AR Lacertae shows its spots. Of course, spot details are unknown, so the simulation shows two broad areas that represent heavily spotted regions, according to the approximate situations in 1977 (top left) and 1981 (top right). Changes from 1977 (upper curve) to 1981 can easily be seen in the machine-generated light curves of the lower panel.

Table 1. Parameters determined from eclipsing binary light curves.

Parameter	Comment
Orbital period, P	$\mathrm{d}P/\mathrm{d}t$ may also be a parameter
Reference time, t_0	Usually the time of a conjunction
Orbital inclination, i	$i = 0^\circ$ in plane of sky
Surface potentials, ψ_1, ψ_2	Potentials specify surface dimensions (*e.g.* R_1, R_2)
Orbital eccentricity, e	e =(distance between foci)/(length of major axis)
Argument of periastron, ω	Angle between line of nodes and orbit's major axis
Gravity brightening exponents, β_1, β_2	Symbols and definitions differ among authors
Bolometric albedos, A_1, A_2	Discussed in text
Mean surface effective temperatures, T_1, T_2	Temperatures that would exist without reflection effect
Mass ratio, M_2/M_1	Determinable only in favorable circumstances
Bandpass luminosities, L_1, L_2	Conventionally normalized to their sum
Limb darkening coefficients, x_1, x_2, y_1, y_2	Various approximate relations commonly used
Spot latitude, longitude, size, temperature	Spots are circular in most models
Third light, l_3	Represents any third source—usually a star

learned by matching good models to observations.

Star figures and system morphology

Tidal dissipation has dragged many eclipsing binaries into SYNCHRONOUS ROTATION (for brevity, co-rotation), which for circular orbits means that axial rotation and orbital revolution have the same period. Their tidal distortions are static in a co-rotating frame, with stretching along the line of centers. Rotation produces polar flattening, so the combined tidal and rotational figure is egg like with the narrow end toward the companion and the polar dimension smaller than the side dimension. The shape can often be approximated by a triaxial ellipsoid (a *geometrical model*), although not in the more distorted cases.

Today's *physical models* are based on level surfaces of constant potential energy per unit mass that can be larger, smaller or accurately match certain critical surfaces that have important roles in light curve analysis as well as in binary star evolution. The configuration for co-rotation, where the entire system rotates with one angular velocity, is most easily viewed in the co-rotating frame. A null effective gravity point must exist on the line of centers between the stars where the opposing star gravities plus centrifugal force add to zero. It marks a saddle point in potential, with the downhill direction away from the null gravity point toward both stars. The *inner critical surface* passes through the null point and is the largest equipotential a star can fill without spilling gas onto its companion. It consists of a *limiting lobe* for each star, and the term *contact* in binary star morphology refers to contact of a star with its lobe rather than of one star with another. Ordinarily a star cannot be larger than its limiting lobe because it would then rapidly lose material, although stable overcontact configurations exist

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

with both stars exceeding their limiting lobes, neither star being a willing receptacle for material from the other. If undercontact, accurate contact and overcontact are respectively symbolized **U**, **A** and **O**, then the binary combinations **UO** and **AO** are effectively ruled out except for extremely brief intervals. Otherwise pressurized layers would face onto a vacuum. The morphological categories that are ordinarily attainable are called *detached* (**UU**), *semidetached* (**UA**) and *overcontact* (**OO**). No known evolutionary process leads to the **AA** case in co-rotating binaries and any evolutionary size change would convert **AA** to **UU**, **UA** or **OO**. However, the **AA** case (*double contact*) probably occurs in non-synchronous binaries when evolutionary expansion causes one star to fill its lobe while fast rotation causes the other lobe to shrink onto its star. RZ Sct and U Cep may be examples. There also is an outer critical surface that marks the largest an overcontact binary can be without having catastrophic flow from a 'back' null point of effective gravity. That point is behind the less massive star on the line of centers. All cases are illustrated in figure 4.

Analysis

A modest number of simple rules connect light curves with system characteristics. Assume the time scale to be in orbital phase (*i.e.* folded on the period) and the brightness scale to be in light (not stellar magnitude). Then for circular orbits the two eclipses have equal durations, while for eccentric orbits the eclipse that occurs nearer to apastron is the longer one. In the circular case for spherical stars, the sine of half the phase duration of either eclipse, $\sin \Theta_e$, is a lower limit on the sum of relative radii, with direct application if $i = 90^\circ$. Allowing for inclination, the relation is $(R_1 + R_2)/a = (\cos^2 i + \sin^2 i \sin^2 \Theta_e)^{1/2}$. An obvious point is that the ratio of light lost to light remaining at the bottom of a total eclipse is essentially the luminosity ratio of the smaller to the larger star, in a given observational bandpass. This rule becomes virtually exact in the absence of tides and mutual irradiation and allows exceptionally accurate determination of luminosity *ratios*. The ratio of radii is determined most strongly from a reasonably deep annular eclipse, combined with a total eclipse. Then the ratio of light loss in the annular eclipse to the light remaining in totality is nearly the square of the ratio of smaller to larger star radii, with small discrepancies due to limb darkening and other brightness distribution effects. For circular orbits, the eclipses are equally spaced, by half a cycle, while for eccentric orbits they are equally spaced only if we 'look along the major axis', with $\omega = 90^\circ$ or 270°. The argument of periastron ω tells how the orbit is situated in angle within its own plane. If the orbit rotates (apsidal motion) then the eclipses have excursions about the 0.0 and 0.5 cycle points that are 180° out of phase (one goes 'left' while the other goes 'right'). The position angle of the nodal line, Ω, cannot be found from a light or radial velocity curve because neither is affected by a rotation of the binary about the line of sight. However, Ω can be found from polarimetric variation for a few binaries.

In a physical light curve model, the gravitational potential energies of the two stars, ordinarily considered as point masses, and centrifugal potential energy are added to form a total potential energy per unit mass, ψ, with

$$\psi = \psi(\mathcal{R}, \theta, \phi, M_1, M_2, F_r, D). \qquad (1)$$

Here θ, ϕ are latitude and longitude and M_1, M_2 are the masses. One usually works with a dimensionless version whose length unit is the orbital semimajor axis, a, and in which mass ratio replaces the absolute masses. The rotation parameter F_r and instantaneous separation D generalize ψ to non-synchronism and eccentric orbits at the cost of certain, usually inconsequential, approximations. To specify a star surface, the radial coordinate, $\mathcal{R}$, is required to follow a surface of constant ψ. Equation (1), or in practice the dimensionless form, is numerically inverted with fixed $\psi, M_2/M_1, F_r, D$ to compute a relative radial coordinate, $r = \mathcal{R}/a$, as a function of θ and ϕ (i.e. to compute a grid of surface points). Thus equation (1) defines a family of surfaces in the parameter ψ, one of which corresponds to the actual surface of a given star, with ψ_1, ψ_2 replacing the mean star radii of geometrical models as star size parameters. The magnitude and direction of the potential gradient, $\nabla\psi$, respectively determine local effective gravity and surface orientation. Many schemes have been published for integrating the light from these surfaces while accounting for eclipses and the various surface brightness effects. Such computations became practical with the machines of ca 1970.

Morphology can be built into light curve analyses. For example, it might be reasonably certain that a binary is semidetached, although a discussion of reasons would exceed available space. If so, the contact star's surface potential is not a free parameter but is the lobe potential and can be calculated from other parameters, most notably the mass ratio. The functional relation thus defined can be used to eliminate an entire dimension of incorrect solutions. The lobe filling condition can be exploited not only for general solution improvement but sometimes to determine particular parameters that otherwise would not be derivable. The prime example is the *photometric mass ratio*. Ordinarily a mass ratio estimate requires some means to find the relative location of the center of mass, which a light curve does not provide. However, light curves of semidetached and overcontact binaries do tell the location of the null point of effective gravity, which is determined by the mass ratio. Lobe size is fixed by the condition that the lobe contains the null point. Thus, in a semidetached binary, star size determines lobe size, which in turn determines mass ratio. For overcontact, the dumbbell's overall shape (ratio of bulge sizes) is conditioned by the pinch of its waist around the null point, so essentially R_2/R_1 determines mass ratio. A common misconception is that a photometric mass ratio mainly derives from ellipsoidal variation. However, the actual information sources are eclipses, particularly total-annular

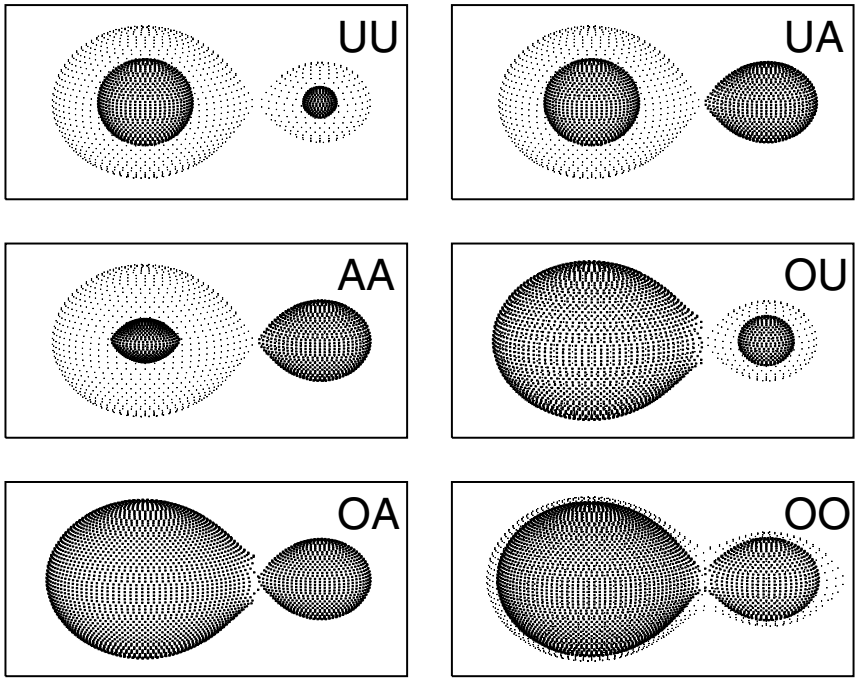

Figure 4. All combinations of undercontact (**U**), accurate contact (**A**) and overcontact (**O**) are illustrated. Stars are shown with the larger dots and limiting lobes as ghostly surfaces (smaller dots). The well-known detached (**UU**), semidetached (**UA**) and overcontact (**OO**) cases are at top left, top right and lower right, respectively. The overcontact binary is surrounded by an outer contact surface that limits its maximum size. The newer category of double contact (**AA**) is at middle left, where the actual limiting lobe coincides with the star, and the ordinary (co-rotation) lobe also is shown for reference. Double contact binaries have one component limited in size by fast rotation. The **OU** (middle right) and **OA** (lower left) configurations are ordinarily unphysical, as discussed in the text.

eclipses, that determine accurate relative star dimensions. A photometric mass ratio allows one to find all the mass and absolute dimension information that normally requires velocity observations of both components, even when velocities of only one component exist.

Recent and future developments

A new data source has appeared in spinoff from the several gravitational microlens surveys that automatically produce thousands of light curves. Although precision is not as good as for data gathered in the usual way and radial velocities are lacking, observers can sift through the survey light curves to find interesting binaries for more thorough observation. Extra-Galactic eclipsing binaries thus identified and subsequently observed with large telescopes can improve the HUBBLE CONSTANT. Stellar interferometry promises a new era of inroads into the domain dominated by eclipsing binaries. In principle, interferometric images could replace light curve analyses, although the baselines and general capabilities needed for typical distant examples seem beyond forseeable expectations. However, major instrumental advances are on the way. In the nearer term, advanced interferometry will forge connections between the fields of eclipsing and visual binaries.

Although one naturally thinks of eclipses in the observational context of light curves, there are direct links of eclipses to other observations. One link is spectral disentangling, a computationally intensive use of eclipses to isolate entangled binary spectra. Several distinct procedures exist and all achieve good separation of apparently hopelessly blended spectra, sometimes even when there is no phase without serious blending. The essential idea is that each eclipse modulates only one of a blended pair of spectra and does so in a known or determinable way. Disentangling schemes average over random noise very effectively because they not only fit entire spectral windows (as opposed to individual lines) but fit all spectra simultaneously. Another kind of simultaneous solution fits combinations of *types* of observations, such as light, velocity and polarimetry curves. The main advantage is reduced parameter count, as some parameters (*e.g.* eccentricity, mass ratio, inclination) are common to two or more data types. Still another development is rotation measurement from light curves rather than from spectral line broadening, which can sometimes be done because rotation affects star figures and surface brightness distributions and therefore affects eclipse circumstances.

Omissions due to space limitation are covered by the bibliography and include background areas such as history, contributors, the role of computers, 'badly behaved' binaries, famous classical problems,

interconnections with spectroscopic binaries and full descriptions of eclipsing binary categories. Also covered there are further ways to observe eclipses, such as by POLARIMETRY. Disks and other circumstellar structures as well as extended atmospheres and spots of various kinds are also mentioned in the bibliography. However, proper treatments of these items and of exotic new discoveries incorporating white dwarfs, neutron stars and black holes are to be found only in the general literature.

Ecliptic

A great circle on the celestial sphere which represents the apparent annual path of the Sun in its motion relative to the background stars. It is so called because eclipses can occur when the Moon crosses it. Due to the motion of the Earth around the Sun, the Sun appears to move across the celestial sphere, completing one full circuit in a year. The ecliptic, in fact, represents the intersection of the orbital plane of the Earth with the celestial sphere and, because the equator of the Earth is inclined by an angle of approximately $23\frac{1}{2}^{\circ}$ to the orbital plane, it follows that the ecliptic is inclined to the celestial equator by the same amount (the obliquity of the ecliptic). The ecliptic intersects the celestial equator at two points, the vernal equinox and the autumnal equinox.

See also: celestial equator, celestial poles, celestial sphere, equinox, obliquity of the ecliptic.

Ecosphere

The shell-shaped region around a star within which the surface temperature of a suitable planetary body is conducive to the existence of life. Both the diameter and the thickness of the ecosphere depend on the type of star, in particular on its surface temperature. In the solar system the ecosphere extends from just outside the orbit of Venus to just within the orbit of Mars, making Earth the only suitable planet for life, by this definition. (Note that the Moon is in the Sun's ecosphere, but does not possess the conditions to make it suitable for life.) In general, hotter stars have a larger and wider ecosphere; cooler stars a smaller and narrower one. A dwarf star, though, would have a much smaller and narrower ecosphere than a giant star with the same surface temperature.

The traditional concept of an ecosphere as defined above was framed to apply to surface life (on land or in surface oceans) and to lifeforms similar to those familiar on the Earth. In the 1990s it became clear that 'life' in its broadest sense may cover a wider spectrum and may exist in more unusual environments. Micro-organisms known as extremophiles have been found which, as the name implies, thrive in extreme environments, in particular at temperatures much higher or lower than other organisms can tolerate. In addition, there are deep-ocean and subsurface organisms which do not rely on photosynthesis, and can withstand temperatures of 1100 °C and 1200 °C, respectively, at depths of 5 km. It has been speculated that life may exist in the subsurface ocean of Jupiter's satellite Europa, for example. If life does turn out to be possible in this and other 'extreme' environments, the standard definition of ecosphere will need to be rewritten.

Eddington, Sir Arthur Stanley (1882–1944)

Astrophysicist, born in Kendal, Westmorland, England, became Plumian professor of astronomy and director of the Cambridge Observatory. Eddington's work on the theory of relativity was described by EINSTEIN as 'the finest presentation of the subject in any language' and from Greenwich, he led one of the two 1919 solar eclipse expeditions which confirmed the predicted deflection of starlight by gravity. His lifetime's work concerned the internal structure of stars. He discovered the mass–luminosity relationship, calculated the abundance of hydrogen and explained the pulsation of Cepheid variable stars and the very high densities of white dwarfs. He was one of the first to identify nuclear reactions as the source of power in stars. He studied the pressure of the transport of energy through a star by radiation, and showed that above a certain luminosity, the *Eddington limit*, a star cannot through the force of gravity maintain its equilibrium and will disrupt. In his later years he pointed out some surprising numerical coincidences between atomic and cosmological quantities, but his cosmological theory about the reasons why has not been accepted at all.

Education

In surveys of first-year undergraduate science students at British universities, astronomy and space stand out most prominently as the areas of science that attracted the students into science. There is something grand and inspiring about the Universe that motivates young people, and indeed the not-so-young, to study astronomy to a greater or lesser degree.

Science is now taught in virtually all schools. In general astronomy is regarded as a minor part, but it is regarded as important to understand the basic astronomical facts such as that the Earth is spherical, that its rotation causes day and night, that it orbits the Sun and its tilt during the orbit produces the seasons, that we live in a galaxy of stars and that there are other galaxies in the Universe.

Motivated school students can take astronomy as a separate examination subject in many countries; in Britain, for example, there is an annual paper in astronomy in the portfolio of tests (the GCSE) that are taken at about age 15. This encourages the candidate to undertake actual observational programs as well as learning from books. Significantly, however, only the most elementary mathematics is included in the British GCSE—and astronomy is above a mathematical subject.

Local astronomical societies are invaluable in education, because many of them have observatories of their own (see AMATEUR ASTRONOMICAL SOCIETIES) and nearly all of them organise lecture programs with qualified speakers. The programmes may be informal or may be structured as an adult education course.

Of course, public observatories are of immense importance, and in some countries are both common and highly successful—notably in the United States and Japan. In Britain they are rare, perhaps because there is the problem that during a 'public night', when the telescopes are made available, the skies are too often cloudy! A series of robot telescopes now exists for education, placed in good observing sites. In California the most advanced network is based at Mt Wilson Observatory and is called Telescopes in Education (http://tie.jpl.nasa.gov/). The UK is building on Hawaii the 2-metre telescope Faulkes Telescope for public access (http://www.faulkes.com/).

One very important development concerns the spread of planetaria. A PLANETARIUM provides an 'artificial sky'; the viewer sits inside a large dome, and the celestial bodies are shown by means of a special projector. The effect can be amazingly realistic, and in a large planetarium it is hard to remember that you are not looking at the real sky. There are hundreds of planetaria world wide, see the International Planetarium Society at http://www.ips-planetarium.org/

One great advantage of a planetarium is that its sky can be made to show phenomena which the real sky cannot, except under special circumstances, for instance, a total eclipse of the Sun. The sky can be shown as it will be at any hour, and from any part of the world; time travel is easy—one can, for instance, see the sky as it was at the time of the Crucifixion. The movements of the planets can be speeded up, and even the proper motions of the stars can be shown, whereas the real stars are so far away that the constellation patterns remain sensibly unchanged for periods of many lifetimes.

Planetaria have traditionally been based on opto-mechanical projection devices. Recent advances in computer technology are making possible digital projectors, controlled in almost infinite variety by software. The possible shows are almost unrestricted in subject matter, and can range from the purely fun (simulated trips into a black hole for example) to the seriously technical (e.g., teaching navigation).

Many universities cater for astronomy in one way or another, so that a degree can be taken either in 'pure' astronomy or in a modular form (physics and astronomy being a favorite) (see PROFESSION). About 50 UK universities teach astronomy modules in specialist science degrees (i.e. half of them). In the USA, where degree level studies have a higher diversification than in the UK, astronomy is often a popular choice for the science component of a liberal arts degree and for study as a special subject in science degrees.

National astronomical societies (see ASTRONOMICAL SOCIETIES AND PUBLICATIONS) have education subsections, such as the American Astronomical Society's Working Group on Astronomical Education (http://www.aas.org/~wgae/wgae_index.html) and the Royal Astronomical Society's Education Committee. The Astronomical Society of the Pacific is targeted explicitly towards the dissemination of information to the public including through educational programmes (http://www.aspsky.org/education.html).

The International Astronomical Union, through its Commission 46 on the Teaching of Astronomy (http://physics.open.ac.uk/IAU46/) supports a travelling telescope and summer schools for students of astronomy in the developing world, where there is increasing interest. In South Africa, the new African government supports astronomy education as a means to develop the aspirations of the South African people into its modern era.

The US Association for Astronomy Education (http://solar.physics.montana.edu/aae/), the UK Association for Astronomy Education (supported by the Royal Astronomical Society) and the European Association for Astronomy Education (based at the European Southern Observatory) offer events and teacher training in astronomy (http://www.star.ucl.ac.uk/~aae/aaehomep.htm), with the avowed intent to modernise astronomy education in schools.

Effective Temperature Scale and Bolometric Corrections

The conversion from an observational quantity, such as the color index or the spectral type, to the effective temperature ($T_{\rm eff}$) of a star is known as the effective TEMPERATURE SCALE. Bolometric corrections are required in the calculation of the luminosity of a star if the flux from the star has not been observed over the entire ELECTROMAGNETIC SPECTRUM.

The $T_{\rm eff}$ of a star is defined to be the temperature of a BLACKBODY RADIATOR with the same radius and the same total energy output (i.e. luminosity) as the star. Practically speaking, the $T_{\rm eff}$ corresponds quite closely to the temperature of the visible surface of a star. Knowledge of any two of the three variables, $T_{\rm eff}$, radius and luminosity, allows calculation of the third variable. Thus to calculate directly the $T_{\rm eff}$ of a star, both the luminosity and the radius of a star must be known. These two quantities can be found for only a limited number of stars. The luminosity of a star requires knowledge of the bolometric flux of a star (which includes radiation across the entire electromagnetic spectrum) and thus requires observations from space, and is well known for only a few hundred stars. Fluxes are thus for the most part measured in only a limited region of the spectrum—usually the optical. To derive bolometric fluxes from these measurements, a correction, termed a bolometric correction, is required. The radius of a star requires knowledge of the angular diameter of a star and the distance to the star. Again, this quantity is known for only a limited number of stars. Thus, for most stars, the $T_{\rm eff}$ cannot be determined in a fundamental way. Astronomers must therefore rely on other methods, including measuring a proxy for the $T_{\rm eff}$ (for instance the color index or the spectral type), and then finding a way to convert from this proxy to the $T_{\rm eff}$. This conversion is called the effective temperature scale.

The determination of the effective temperature

The most straightforward way to derive the effective temperature scale, i.e. the conversion between an observational quantity such as the B–V color index, or the spectral type of a star, and the $T_{\rm eff}$ is to determine the $T_{\rm eff}$ for as many stars as possible over a wide range of temperatures, and then relate these effective temperatures to the observed quantity. How does one determine the $T_{\rm eff}$ of a star?

Fundamental effective temperatures

The fundamental way to derive the $T_{\rm eff}$ of a star is to use the Stefan–Boltzmann law in the following form:

$$L = 4\pi\sigma R^2 T_{\rm eff}^4 \qquad (1)$$

where L is the luminosity of the star, σ is the Stefan–Boltzmann constant and R is the radius of the star. Unfortunately, neither the luminosity nor the radius can be measured directly. What can be measured from the Earth are the monochromatic flux, F_ν, which is the energy from the star incident on a unit area on the surface of the Earth per unit time per unit frequency interval, and the angular diameter (θ_D) of the star. These quantities can be related to the $T_{\rm eff}$ in the following way:

If $\mathcal{F}_\nu$ represents the flux emitted from the stellar surface, and F_ν represents, as above, the flux from the star measured at the Earth, then it necessarily follows, from the conservation of energy (ignoring interstellar extinction and absorption by the atmosphere of the Earth), that

$$4\pi r^2 F_\nu = 4\pi R^2 \mathcal{F}_\nu$$

where r is the distance to the star. Integrating the flux at the Earth over the entire electromagnetic spectrum yields

$$\int_0^\infty F_\nu \, {\rm d}\nu = F_{\rm bol}$$

where $F_{\rm bol}$ is the total or bolometric flux from the star, and

$$L = 4\pi R^2 \int_0^\infty \mathcal{F}_\nu \, {\rm d}\nu = 4\pi\sigma R^2 T_{\rm eff}^4.$$

Consequently

$$F_{\rm bol} = (R/r)^2 \sigma T_{\rm eff}^4.$$

Now, the angular diameter of a star, measured from the Earth is $\theta_D = 2(R/r)$. Thus, finally

$$F_{\rm bol} = \tfrac{1}{4}\theta_D^2 \sigma T_{\rm eff}^4.$$

Angular diameters can be measured for nearby stars using a number of techniques, including optical phase-coherent or amplitude interferometry, intensity interferometry, speckle interferometry (see INTERFEROMETRY: GROUND) and lunar OCCULTATIONS. It is possible to determine actual radii of stars from the analysis of ECLIPSING BINARY STARS. To determine the bolometric flux of a star, its flux must be observed over a wide range of frequencies in the electromagnetic spectrum. For most stars (except for the very hottest stars), the majority of the flux from the star is concentrated in the wavelength range ~100 nm (ultraviolet) to ~12 μm (infrared). This requires observations from spacecraft, as the ultraviolet and much of the infrared are strongly absorbed by the Earth's atmosphere. Spacecraft which have been useful in this regard include the International Ultraviolet Explorer (IUE), the Sky Survey Telescope on the ESRO TD1 satelite, the Infra-Red Astronomical Satellite (IRAS), the Infrared Space Observatory (ISO) and the Hubble Space Telescope (HST).

Bolometric corrections

If the bolometric flux of a star has not been measured directly, it is still possible to estimate it from the stellar flux over a much more limited wavelength range using bolometric corrections. Bolometric corrections are usually defined in terms of magnitudes. Thus, if M_V represents the absolute magnitude of a star measured in the Johnson

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

photometric V-band, and $M_{\rm bol}$ the absolute bolometric magnitude calculated from the entire spectrum, then the bolometric correction ($B.C.$) is defined as

$$B.C. \equiv M_{\rm bol} - M_V. \quad (2)$$

Then the luminosity of the star can be calculated from the equation

$$\log\left(\frac{L_*}{L_\odot}\right) = 0.4[M_V(\odot) - M_V(*) + B.C.(\odot) - B.C.(*)] \quad (3)$$

where the $\odot$ quantities refer to the Sun. If the radius of the star is known, then the $T_{\rm eff}$ follows from equation (3) and equation (1).

Tables of bolometric corrections may be calculated using stars for which complete flux distributions are available, or from theoretical stellar flux distributions. Equation (2) can be rewritten

$$B.C. = 2.5 \log \frac{\int_0^\infty F_\nu S_\nu \, {\rm d}\nu}{\int_0^\infty F_\nu \, {\rm d}\nu} + C_1$$

where S_ν is the photometer response for the wavelength band of interest (in equation (2), the Johnson V-band). C_1 is an arbitrary constant which is usually selected according to convention. The most commonly used convention selects C_1 so that the $B.C.(\odot) = -0.07$. Another convention selects C_1 so that the minimum $B.C.$ is zero, and yet another sets C_1 so that the $B.C.(\odot) = -0.19$. Which convention is chosen (in light of equation (3), where the *difference* in the bolometric corrections of the Sun and the star is the relevant quantity) is not important, just so long as one is consistent. Bolometric corrections are usually tabulated against B–V or the spectral type. When tabulated against B–V the $B.C.$ does not show a strong dependence on the luminosity type of the star. Table 1 gives a recent tabulation of the bolometric correction versus B–V for dwarf and giant stars. Supergiants deviate slightly from the values given in this table. Table 2 tabulates the bolometric correction versus spectral type. In this table separate scales for the different luminosity classes are given. In both tables the convention that $B.C.(\odot) = -0.07$ is adopted. Notice that for both cool and hot stars, the magnitude of the bolometric correction is quite large. This is because, for these stars, most of the flux is outside the optical region. For such stars, the bolometric correction is not very reliable. Instead of equation (2) for the definition of the bolometric correction some sources use the equation $B.C. \equiv M_V - M_{\rm bol}$, in which case the bolometric corrections are the negatives of those given in tables 1 and 2.

Other methods of determining the effective temperature

Many stars are too far away for the measurement of their angular diameters, and/or many have not been adequately observed in the ultraviolet or in the infrared. For these stars other techniques are available to determine their effective temperatures, but not in a fundamental way.

Table 1. $T_{\rm eff}$ and bolometric corrections as functions of B–V.

For all but the hottest stars the observed flux distribution (i.e. F_ν or F_λ versus wavelength) of a star may be compared with theoretical flux distributions from model STELLAR ATMOSPHERES. The best determinations of $T_{\rm eff}$ using this method are for stars which have been observed over a wide wavelength range. Figure 1 shows an example of such a fit for the star β Leo, which has been observed in the ultraviolet (using the IUE satellite), and the optical and near-infrared using ground-based telescopes. Even if a star has not been observed outside the optical range, ground-based observations can be used to obtain an adequate fit with theoretical flux distributions. Because theoretical models are used, this method of determining the $T_{\rm eff}$ cannot be regarded as fundamental; the derived effective temperatures are only as good as the models.

For very hot stars (for example the early O-type stars), the $T_{\rm eff}$ is so great that the maximum of the continuum flux of these stars is in the extreme UV, and thus even space-based observations fall on the long-wavelength or Rayleigh–Jeans tail of the flux distributions of these stars, the slope of which is very insensitive to the $T_{\rm eff}$. For such stars, it is necessary to adopt an entirely different technique to estimate the effective temperature. This technique

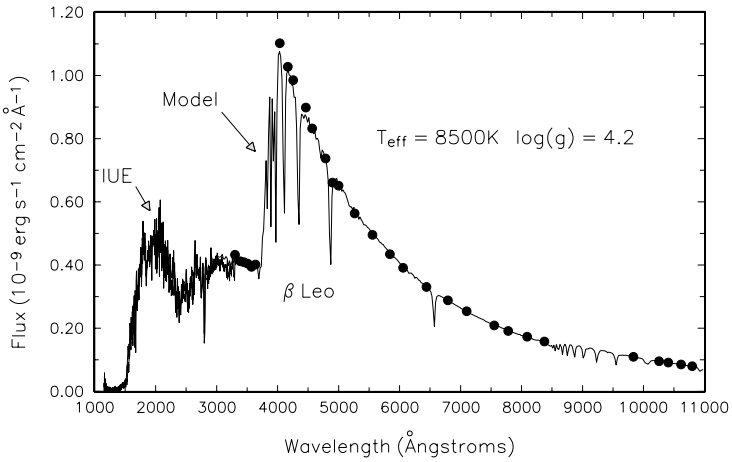

Figure 1. A model fit to the observed fluxes of the star β Leo. The full circles indicate ground-based spectrophotometry in the optical and near-infrared. The data marked IUE (extending from 1100 Å to 3200 Å) represent an ultraviolet spectrum of the star obtained with the International Ultraviolet Explorer (IUE) satellite, while the solid line extending from 1100 Å to 11000 Å (and partially obscured by the IUE data) represents the fitted model calculated with the model stellar atmospheres program ATLAS9. The effective temperature of the star is determined to be 8500 K.

involves fitting the spectral line profiles of lines of singly ionized helium (He II), neutral helium (He I) and hydrogen with theoretical line profiles. Such comparisons require the calculation of non-LTE stellar atmosphere models which include the effects of radiation scattered back from the stellar wind onto the photosphere, the so-called wind blanketing effect. Including the effects of wind blanketing can change the effective temperature by as much as 10%.

Lacking an observed flux distribution, certain spectral features can be used to determine the effective temperature. For instance, in the B-type stars the size of the Balmer jump, a discontinuity near 3650 Å in the stellar flux due to the photoionization of hydrogen, is temperature sensitive. In the F- and G-type stars, the profiles of the Balmer lines of hydrogen are quite sensitive to the $T_{\rm eff}$. In the late-type stars (G- and K-type stars), ratios of the line depth of lines due to neutral metals can be quite sensitive to the $T_{\rm eff}$ if one of the lines has a low excitation potential while the other has a relatively high excitation potential. In such a case, the line with the low excitation potential grows rapidly in strength with decreasing $T_{\rm eff}$, while the high excitation potential grows less rapidly or even declines in strength. Such techniques can yield a temperature precision on the order of 20 or 30 K, although the absolute temperature is more uncertain.

The effective temperature scale

Once the effective temperatures of a sufficient number of stars have been determined (preferably in a fundamental way), the relationship between an effective temperature proxy, such as the $B{-}V$ index and the effective temperature, can be tabulated. This is known as the effective temperature scale. One recent tabulation is given in table 1. Notice the unsuitability of the $B{-}V$ color index for this purpose for the very hot stars; a small change in $B{-}V$ yields a large change in the $T_{\rm eff}$. Some improvement can be obtained by using the $U{-}B$ index, but both are subject to the same fundamental limitation mentioned above: for the hottest stars, observations in the optical and even the near-UV lie too far out along the temperature-insensitive Rayleigh–Jeans tail of the flux distribution. As an alternative, tabulations of the $T_{\rm eff}$ and the bolometric corrections are often made against the spectral type. Table 2 contains such a tabulation derived from a number of recent sources. For the cool, luminous stars, effective temperatures are not yet well determined. In the B-, A-, and early F-type stars, the $T_{\rm eff}$ and bolometric corrections are not strongly dependent on the luminosity class.

Applications of the effective temperature scale and future developments

Arguably the most important diagram in stellar astronomy is the HERTZSPRUNG–RUSSELL (HR) DIAGRAM. In its theoretical form, this diagram plots stars in the $T_{\rm eff}$, luminosity plane. In its most common observational form, also known as the color–magnitude diagram, stars are plotted in the color index (commonly $B{-}V$), absolute visual magnitude (M_V) plane. The HR diagram is the arena on which much of modern-day stellar astrophysics takes place. In particular, stellar evolutionary tracks and isochrones calculated from theoretical models are plotted on the HR diagram. To compare these theoretical calculations with observations of real stars and clusters of stars it is necessary to convert from the theoretical quantities of $T_{\rm eff}$ and luminosity to $B{-}V$ and M_V or other similar observed quantities. Indeed, one of the greatest barriers to the advancement of stellar evolutionary theory is the inaccuracy of our knowledge of the effective temperature scale.

Determination of the $T_{\rm eff}$ is often the first step to the derivation of other fundamental parameters of a

star. For instance, knowledge of the $T_{\rm eff}$, the luminosity (from M_V and bolometric corrections via equation (3)) and the surface gravity, which can be determined from spectral analysis, leads to the radius and mass of the star. Knowledge of the mass can then be used, in conjunction with stellar evolutionary theory, to determine the age of the star.

The effective temperatures and bolometric corrections for the hottest and the coolest stars are still uncertain. The newly launched FAR ULTRAVIOLET SPECTROSCOPIC EXPLORER (FUSE) satellite (which has a spectral coverage of 905–1195 Å) helps to sample more of the energy distributions of the hottest stars, and can thus help in the determination of the effective temperatures. This, plus continual advances in stellar atmosphere models for these stars, should lead to a significant improvement in our knowledge of the fundamental parameters of these stars in the near future. The determination of fundamental effective temperatures for the coolest stars, especially the HIGH-LUMINOSITY STARS, will likely continue to be problematical, as the very definition of the radius and the $T_{\rm eff}$ in the very extended atmospheres of these stars is difficult.

Effelsberg Radio Telescope

The 100 m diameter radio telescope has been operated by the MAX-PLANCK-INSTITUT FÜR RADIOASTRONOMIE since 1972 near Effelsberg, Germany. The telescope is fully steerable and its pioneering 'homologous' design minimizes elevation-dependent gravitational deformations, enabling routine observations to wavelengths as short as 6 mm. Scientific programs include high-sensitivity continuum surveys, extensive polarization studies of our own and external galaxies, pulsar research, and atomic and molecular line spectroscopy. The telescope frequently participates in VLBI observations.

Egg Nebula (CRL 2688)

A planetary nebula in the constellation Cygnus, position RA 21^{h} 02.3^{m}, dec. $+36^{\circ}$ $42'$. It is young, possibly having left its red giant phase only a few hundred years ago. The central star, which is obscured by dust, is emitting powerful jets and has shed several shells of material.

Einstein Observatory (HEAO-2)

The second in the series of HIGH ENERGY ASTROPHYSICAL OBSERVATORIES was launched by an Atlas-Centaur rocket on 13 November 1978. Soon after its insertion into a 470 km circular orbit inclined at 23.5º to the equator, HEAO-2 was named the Einstein Observatory, in celebration of the centenary of Albert Einstein's birth.

This groundbreaking NASA X-ray mission revolutionized X-RAY ASTRONOMY. As the first satellite to be equipped with focusing X-ray mirrors, Einstein not only observed sources 10 000 times fainter than its predecessor, UHURU, but it was the first observatory to image X-ray sources.

The four nested paraboloid–hyperboloid mirrors of the grazing-incidence telescope (the largest had a diameter of 58 cm) were able to focus incoming X-rays with energies in the range 0.25–4 keV (see GRAZING INCIDENCE OPTICS). The photons were then analyzed by four interchangeable instruments that could be rotated into the focal plane of the telescope. The field of view varied with the X-ray energy, but was typically about one square degree.

Einstein carried five main instruments:

(1) The High Resolution Imager (HRI) provided an imaging capability with a spatial resolution of approximately 2 arcsec, but had a field of view less than half a degree in diameter.
(2) The Imaging Proportional Counter (IPC) had a greater sensitivity than the HRI and covered the entire field of view of the telescope, but it had a poorer spatial resolution (approximately 1 arcmin) and a very limited spectral capability.
(3) The Solid State Spectrometer (SSS) had a moderate spectral resolution and a 6 arcmin diameter circular field of view.
(4) The Focal Plane Crystal Spectrometer (FPCS) provided high spectral resolution in selected energy bands.
(5) The Monitoring Proportional Counter (MPC) measured the 1–20 keV X-ray flux of the source(s) being observed simultaneously by the telescope.

The leader of the project and the principal investigator for all five instruments was X-ray pioneer RICCARDO GIACCONI.

The first object studied by Einstein was the BLACK HOLE candidate Cygnus X-1. More than 5000 X-ray sources were subsequently catalogued during the observatory's 30-month operational life—including more than 100 hot, young stars in the ORION NEBULA alone. Einstein's ability to detect faint sources meant that it was able to study objects such as SUPERNOVA REMNANTS, X-RAY BINARIES, GALAXY CLUSTERS, ACTIVE GALAXIES and QUASARS. Its high spatial resolution meant that many of these could be linked to optical counterparts for the first time.

Einstein's observations influenced stellar models by showing that the X-ray flux from many stars was thousands of times greater than predicted (see SOLAR–STELLAR CONNECTION). Complex shells of X-ray emitting gas were mapped around several supernova remnants, while 'on–off' emissions from the spinning X-ray PULSAR at the heart of the CRAB NEBULA were also studied. Other supernova remnants were discovered in the LARGE MAGELLANIC CLOUD.

The observatory also confirmed the existence of X-ray sources in both the spiral arms and the nucleus of the ANDROMEDA GALAXY, those near the center being much more luminous. A powerful X-ray source was detected at the center of the radio galaxyCENTAURUS A, while additional X-ray emissions were aligned with its optical jet. Other studies revealed clouds of extremely hot gas surrounding some members of galaxy clusters and filling the space between them (see COOLING FLOWS). Formerly unseen emissions from distant quasars were also revealed by extended observations, indicating that the diffuse X-ray background may be caused by numerous faint sources.

The mission ended in April 1981, when the satellite ran out of attitude control gas. It reentered the atmosphere on 25 March 1982. (see X-RAY TELESCOPES, NEUTRON STARS and NGC 4151)

Einstein, Albert (1879–1955)

Physicist born in Ulm, Württemberg, Germany, described the photoelectric effect (for which he received the Nobel prize in 1921) and created the theory of special relativity in 1905 in his spare time, while an employee of the Swiss patent office. The theory of relativity was based on two hypotheses, that the laws of physics had to have the same form in any frame of reference and that the speed of light remained constant in all frames of reference. He deduced that mass and energy were equivalent. Sought to extend the special theory of relativity to phenomena involving acceleration using the principle of equivalence, in which gravitational acceleration was held to be indistinguishable from acceleration caused by mechanical forces. Gravitational mass was therefore 'equivalent' to inertial mass. While a professor in Prague he predicted the gravitational deflection of light, for example how light from a distant star, passing near the Sun, would appear to be bent slightly, shifting the star's apparent position away from the Sun. This was proposed as the first experimental evidence in favour of Einstein's theory and verified by EDDINGTON's and DYSON's observations at the solar eclipse of 1919. Developed the general theory of relativity while at Zurich and Berlin. The success of the 1919 test of relativity began Einstein's establishment as a scientific icon, with the London *Times* headlining its account 'Revolution in science—new theory of the universe—Newtonian ideas overthrown'. By contrast his work in Berlin was disrupted by demonstrations with an anti-Jewish taint, and eventually Einstein took up a post at Princeton as the Nazis took power. At Princeton he began his work to unify the laws of physics, an ambitious, possibly over-ambitious, task which physicists continue. Became active in the peace movement and took on the role of a wise and independent scientific counsellor to the world. His name is taken for many institutions etc, perhaps the most important astronomically being the Einstein x-ray astronomy satellite.

EISCAT

The EISCAT Scientific Association is an international research organization operating three geophysical research incoherent scatter radar systems, an ionospheric heater and a dynasonde in northern Scandinavia. It is funded and operated by the research councils of Norway, Sweden, Finland, Japan, France, the United Kingdom and Germany.

Two of the VHF and UHF radar transmitters are located close to the city of Tromsø in Norway, while the third, which became operational in 1996, is located near Longyearbyen on the Arctic island of Spitzbergen. The radars measure plasma densities, temperatures and velocities in the polar and auroral ionosphere.

Ejecta

Material thrown out by an impact on the surface of a planetary body, particularly by a crater-forming event. Ejecta consists mostly of material excavated from the body that has been struck. It can form rays, extending radially from the crater; an *ejecta blanket*, a continuous deposit of ejecta surrounding the crater; or secondary craters, caused by larger fragments of ejected debris. Material that has been on a surface tends to darken with age through exposure to radiation, so ejecta, which consists of fresh subsurface material, is frequently bright by contrast.

See also: craters, ray, secondary crater.

Electromagnetic Radiation

Radiation, consisting of an electric and a magnetic disturbance, which travels in a vacuum at a characteristic speed known as the velocity of light (approximately 300 000 km s^{-1}). In other words, a light wave consists of periodically varying changes in electric and magnetic fields.

Usually electromagnetic radiation is thought of as a wave motion, the distance between successive crests being the wavelength. Thus, for example, visible light has a wavelength of a few hundred nanometers (a nanometer $= 10^{-9}$ meters), compared with a radio wave with a wavelength of the order of meters. The number of wavecrests passing a fixed point in one second is the frequency. This equals the velocity of light divided by wavelength. Thus, short wavelength corresponds to high frequency.

The full range of electromagnetic radiation is divided, in order of increasing frequency and decreasing wavelength into: radio waves, microwaves, infrared rays, visible light, ultraviolet light, x-rays and gamma rays.

Electromagnetic radiation may also be described in terms of quanta or photons ('packets' or 'particles' of energy). The energy associated with electromagnetic radiation is inversely proportional to wavelength and directly proportional to frequency. Thus, the shorter the wavelength, the more energetic the photon.

The human eye responds to different wavelengths of light by recognizing different colors (red light has a longer wavelength than blue light).

Most of our information about the universe has been obtained by measurements of electromagnetic radiation of one kind or another reaching us from space.

Electromagnetic Spectrum

The complete range of electromagnetic radiation, from the shortest to the longest wavelength. By convention, the electromagnetic spectrum is divided into a number of different wavebands. From the shortest to the longest wavelengths, the broad principal divisions are: gamma rays (wavelengths shorter than 0.01 nm), x-rays (0.01–10 nm), ultraviolet (10–390 nm), visible (390–700 nm), infrared (700 nm–1 mm), radio (1 mm upwards). Although human eyes are sensitive only to wavelengths in the range from about 390 nm to about 700 nm, the 'optical' region of the spectrum is generally taken to encompass the wider waveband from 310–1000 nm (310 nm–1 μm). Further subdivisions in common astronomical usage are: hard x-ray (0.01–0.1 nm), soft x-ray (0.1 nm–10 nm), extreme ultraviolet (EUV, or XUV: 10 nm–91 nm), near-infrared (1–4 μm), mid-infrared (4–40 μm), far-infrared (40 μm–350 μm; i.e. 40 μm–0.35 mm), sub-millimeter (0.35–1 mm), millimeter-wave (1–10 mm), microwave (1 mm–0.3 m).

Most incoming radiation is absorbed by the atmosphere or reflected back into space, but radiation in the wavelength ranges 310 nm–1100 nm, and from about 2 cm to about 30 m, can penetrate to ground level, these bands being known, respectively, as the optical and radio 'windows'. A few narrow bands of radiation in the near- and mid-infrared regions of the spectrum, and radiation in the sub-millimeter and millimeter-wave regions, can be studied from good, high-altitude, observing sites.

Electron

A stable elementary particle with a mass of 9.1091×10^{-31} kg (equivalent, in energy terms, to 0.511 MeV) and a negative charge of 1.602×10^{-19} coulomb. The electron has a spin of 1/2 (in units of the Planck constant, h, divided by 2π) and is a member of the lepton family. Electrons can exist either as free particles or as the negatively charged components of atoms. A complete atom contains equal numbers of negatively charged electrons and positively charged protons and is, therefore, electrically neutral. A flow of electrons (for example, along a wire, or in some other conducting medium) constitutes an electric current. For historical reasons, electrons are sometimes referred to as beta particles, and a stream of electrons as beta radiation.

In the simplest model of the atom (the Bohr model), electrons are considered to travel around the atomic nucleus (which consists of protons and neutrons) in certain specific orbits, each of which corresponds to a particular energy level of the atom. If an electron absorbs a quantity of energy equal to the difference in energy between two levels, it will jump up to a higher ('excited') level. When an electron drops from a higher level to a lower one, energy is emitted in the form of a photon. In complex atoms, the constituent electrons are located in concentric shells, the maximum number of electrons in each shell being dictated by quantum mechanics and the Pauli exclusion principle. The maximum permitted number of electrons in the innermost shell is 2 (in this case, the two electrons must have opposite spins), in the second shell, 8, in the third, 18, and so on. When a shell contains the maximum number of electrons, it is said to be filled. The innermost shells usually fill up first, any remaining electrons being available to take part in chemical interactions with other atoms (these electrons are called valence electrons). Atoms with filled shells, such as helium (2 electrons) and neon ($2 + 8 = 10$ electrons), are particularly stable, more energy being needed to raise one of their electrons to a higher level, or to remove it altogether, than is the case with atoms that have partially filled outer shells.

The magnitude of the charge on the electron (or 'electronic charge'), which is denoted by the symbol 'e', is used as the unit for describing the charges on subatomic particles and atomic nuclei.

Electronvolt

A unit of energy that is used to describe the energies of subatomic particles and photons, or the energy levels of atoms. One electronvolt (symbol eV), which is the kinetic energy gained by an electron when it is accelerated through a potential difference of one volt, is equivalent to 1.602×10^{-19} J. Commonly used multiples are keV (10^3 eV), MeV (10^6 eV), and GeV (10^9 eV).

Electroweak Force

The united force that encompasses the electromagnetic force and the weak nuclear force. The unification of these two forces is described by a theory that was devised during the 1960s by Sheldon Glashow, Steven Weinberg and Abdus Salam according to which, at high enough energies, the electromagnetic force and the weak nuclear interaction behave in exactly the same way.

The electromagnetic force is conveyed between real particles by virtual photons (photons which come into existence in accordance with the Heisenberg uncertainty principle). According to Glashow, Weinberg, and Salam, the weak nuclear interaction, which gives rise to radioactive decay, is conveyed (or 'mediated') by very massive virtual particles, the W^+, W^-, and Z^0 bosons. The range of a force is determined by the masses of its force-carrying particles (the higher the mass, the shorter the range). Because the electromagnetic force is conveyed by photons, which carry energy but have zero rest-mass, it is a long-range force (a virtual photon of zero energy can travel an infinite distance). Because the W and Z particles have masses in the range 88 to 100 times that of the proton, their range is very small (less than 10^{-17} m). Electroweak theory predicts that at energies in excess of about 100 GeV, W and Z bosons are produced as frequently as photons and the two forces (electromagnetic and weak) behave as a unified force. The discovery of W and Z particles, in high-energy experiments carried out in 1983 using the large proton synchrotron at CERN (the European particle physics laboratory near Geneva), provided strong confirmation of electroweak theory.

Element, Chemical

A substance composed of atoms, each of which has the same atomic number (i.e. contains the same number of protons in its nucleus), and which cannot be broken down by chemical processes into two or more other substances. The identity of a chemical element is determined by its atomic number, its chemical properties being determined by the arrangement of the electrons in the various shells that surround the nucleus (in a complete, neutral, atom, the number of orbiting electrons is equal to the number of protons in its nucleus). Although all atomic nuclei of the same element contain the same number of protons, they may contain differing numbers of neutrons and may, therefore, have different mass numbers (the mass number being the total number of protons and neutrons in the nucleus). Atoms of the same element with different mass numbers are called isotopes.

Each chemical element is denoted by a chemical symbol. For example, hydrogen is denoted by H, helium by He, carbon by C, iron by Fe, and so on. The basic symbol is amplified by the addition of the mass number (A) as a superscript and the atomic number (Z) as a subscript. Thus, an element, X, would be denoted, symbolically, by ${}^{A}_{Z}\mathrm{X}$. For example, hydrogen (with one proton and no neutrons in its nucleus) is represented by ${}^{1}_{1}\mathrm{H}$, helium (with two protons and two neutrons, so that $A = 4$ and $Z = 2$), by ${}^{4}_{2}\mathrm{He}$, iron (26 protons, 30 neutrons), by ${}^{30}_{26}\mathrm{Fe}$, and so on. Of the 92 'naturally occurring' elements, the heaviest of which is uranium, 90 have been found on Earth. The remaining two (technetium and prometheum) have been synthesized experimentally and have also been identified in the spectra of certain stars. In addition, there are at least 15 transuranic ('beyond uranium') elements, elements with atomic numbers greater than 92, which have been synthesized by bombarding various isotopes with (usually) neutrons or alpha particles. A few of the transuranic elements, all of which are radioactive, have been found in nature in microscopic trace quantities.

See also: atom, cosmic abundance of elements, electron, isotope, neutron, proton, radioactivity.

Elementary Particles

Particles that at one time were thought to be the most basic, indivisible, building blocks of atoms and all forms of matter. This category of particle includes the stable leptons (i.e. electrons and neutrinos), the stable baryons (i.e. protons and neutrons) and photons. While electrons and neutrinos are still considered to be truly fundamental particles, which have no internal structure and cannot be broken down into smaller components, protons and neutrons are known to be composed of particles called quarks and are not, therefore, fundamental.

Ellipse

The conic section obtained by cutting a right circular cone by a plane which makes an angle relative to the base of the cone less than the angle made by the side. It is an oval curve having within it two points or foci (singular: focus) such that the sum of the distances from each focus to any point on the curve is a constant. The greatest diameter of an ellipse is the major axis (half of this is the semi-major axis), and the least diameter the minor axis. The ellipse is symmetrical about both its axes. The curve when rotated about either axis forms the surface called the ellipsoid of revolution, or a spheroid.

The foci are located on the major axis, one on either side of the center of the ellipse; the greater the separation of the foci, the more flattened the ellipse. A measure of the separation of the foci is given by the eccentricity, e, which can take values between 0 (the circle) and 1 (the case of the parabola). For an ellipse of semi-major axis a and eccentricity e, the distance from the center of the ellipse to either focus is ae.

The path of a heavenly body moving around another in a closed orbit in accordance with Newton's gravitational law is an ellipse. In the solar system one focus of such a path about the Sun is the Sun itself.

Elliptical Galaxies

Elliptical galaxies are smooth, quiescent star-piles, devoid of any of the spectacular structures found in SPIRAL GALAXIES. They have no disk, no spiral structure and only small amounts of the gas and dust. As a result there are no obvious symptoms of continuing star formation: no H II regions or young star clusters. They are the simplest galactic systems comprising just a single component, relatively bright in the center but fading rapidly with increasing radius. Elliptical galaxies are found mostly in the denser regions of the universe, from rich clusters to small groups; truely isolated ellipticals being relatively rare. Figure 1 shows the central region of the Coma cluster which is dominated by a population of ellipticals. The most luminous elliptical galaxies are amongst the brightest galaxies we know of and this, combined with their apparent simplicity, has made them targets of detailed study, not only so that we can understand their own evolution but also so that they can be used as standard candles to determine distances.

The simple structure of elliptical galaxies is reflected in their place in HUBBLE'S CLASSIFICATION. They are characterized by a single number, the ellipticity $\varepsilon = 10(1 - b/a)$, where b and a are the projected angular extent of the short and long axis of the galaxy on the sky. E5 galaxies have a long axis twice that of the short axis and are almost the flattest ellipticals. Some galaxies have been classified E6 and E7 but these have almost always been found to harbor stellar disks. Because the classification depends on the *projected* axial ratio it is not a physical classification. By making the simple assumption that ellipticals have the two long axes equal with the third axis shorter (i.e. they are oblate, like a tangerine) Hubble was able to invert the observed distribution of projected shapes to estimate the true distribution. He estimated that on average ellipticals have a short axis about 65% of the length of the long axis with a dispersion of about 15%. This picture remained current until the late 1970s but has been dramatically revised since then. In recent years attempts to produce a physical classification for ellipticals, and new ways of estimating their intrinsic shapes, have been developed (see later).

In this article I will limit myself to a discussion of classical elliptical galaxies. These range from the brightest galaxies, which are about 40 times as bright as the Milky Way, to dwarf galaxies that are 100 times fainter than the Milky Way and that are typically found as companions to more massive galaxies (e.g. M32, the companion to the Andromeda nebula, M31). I will not include DWARF SPHEROIDAL GALAXIES which are sometimes, erroneously, refered to as dwarf ellipticals. Luminous elliptical galaxies have roughly the same colors as K-giant stars giving them a yellow-orange hue; less luminous galaxies have slightly bluer colours. In appearance and spectral characteristics the bulges of spiral galaxies resemble low-luminosity elliptical galaxies and historically the bulge component of M31 was taken as typical of ellipticals. There are many parallels between ellipticals and bulges and I will compare and contrast them throughout this article.

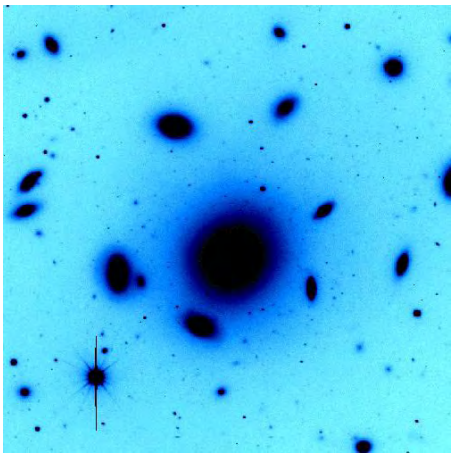

Figure 1. The center of the Coma cluster of galaxies, dominated by the bright elliptical galaxy NGC 4874, which is surrounded by a swarm of fainter, featureless elliptical galaxies. (Image courtesy of the Isaac Newton Group of Telescopes, La Palma and the SMAC (Streaming Motions of Abell Clusters) team.)

In the next section I will draw together the ways in which we have determined the distribution of light and mass as a function of radius within elliptical galaxies, including a discussion of attempts to refine our views of the intrinsic shapes of elliptical galaxies and attempts to detect their massive dark halos. I follow that with a discussion of the special properties of elliptical galaxy cores, where we often find separate components, even rotating in the opposite direction to the bulk of the galaxy, will be discussed. I also discuss the extensive searches for black holes in the centers of ellipticals. Then I describe how we learn about the evolution of the stars that make up ellipticals and how the large-scale properties of elliptical galaxies scale with each other: luminosity, mass, surface density, color, heavy element abundance and rotation. Finally I bring together all of the facets of elliptical galaxies and present the current thinking about how elliptical galaxies formed and evolved.

Structure, size, luminosity and mass

Elliptical galaxies are so called because the contours of constant intensity (called isophotes) are concentric ellipses. This is a very good description of most elliptical galaxies but there are small but significant variations from this simple form. High-quality images show (a) systematic changes in ellipticity with increasing radius, the most common form being a steady increase in the flattening and (b) that the position angle of the major axis of the isophotes changes with increasing radius. In most cases these changes are small (one or two ellipticity classes or a few degrees) but in a small minority they can be dramatic.

The sizes of ellipticals are measured by fitting an analytic form to the fall in brightness (averaged in

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

concentric circular annuli) with increasing radius: the luminosity profile. The most commonly used form was proposed by Gerard de Vaucouleurs in 1948 on the basis of images taken on photographic plates. He proposed

$$I(R) = I_e \exp\{-7.67[(R/R_e)^{1/4} - 1]\}$$
$$= I_e 10^{\{-3.33[(R/R_e)^{1/4}-1]\}}$$

where R_e, the *effective radius*, is the radius that contains half the total light of the galaxy and I_e is the surface brightness (the amount of light from a square arc second of the galaxy) at R_e. This law can be integrated to give a finite total light of $I_{\rm tot} = 7.22\pi {R_e}^2 I_e$. de Vaucouleurs' law, as it is known, fits remarkably well to many of the most accurately determined luminosity profiles of elliptical galaxies and provides a convenient measure of the size and total luminosity of galaxies. Effective radii range from ∼20–30 kpc for giant galaxies to hundreds of pc for the smallest. Total blue luminosities range from 100 billion solar luminosities ($M_B \sim -24$) to 25 million solar luminosities ($M_B \sim -15$). A generalization of this law, proposed by Sersic, which replaces the $\frac{1}{4}$ power by another free parameter $\frac{1}{n}$, fits a wider range of galaxy luminosities and by allowing $n = 1$ even fits the luminosity profile of spiral galaxies well. Other laws have been proposed to describe the presence of a constant surface brightness core in some elliptical galaxies and to account for the extended low surface brightness haloes found in others. Details of these are given in Binney and Merrifield (1998) which is an excellent reference for further reading.

As well as ellipticity changes and isophote twists, elliptical galaxy isophotes exhibit small deviations from pure ellipses that have become the basis for a more physical classification of elliptical galaxies. Accurate determinations of the boxy or disky nature of isophotes have been made consistently even though they arise from contributions to the light of at most a few per cent. Remarkably many properties of elliptical galaxies vary depending on the type and strength of these isophote distortions and recent work links the disky ellipticals in a sequence with lenticular galaxies leaving boxy ellipticals as a separate class. The kinematics, stellar populations, radio power and x-ray emission from elliptical galaxies all show a dependence on isophote shape and these global differences have led to sugestions that these two flavors of elliptical galaxy have different formation histories. Further clues to the formation history of elliptical galaxies are found in the faint, incomplete, shells that have been identified around many galaxies (see figure 2). These weak features may occur in as many as 30% of elliptical galaxies and are thought to be the remnant of a small disk galaxy that has fallen into an elliptical and been destroyed.

Determining the luminosity profile is the first step to calculating the mass of elliptical galaxies. The simplest assumption is that the light traces the mass and so, for a given assumed intrinsic shape, the observed surface brightness (which is the integral along the line-of-sight of the luminosity density) is related to the projected surface mass density by a constant factor, the mass-to-light ratio (M/L) of the stars.

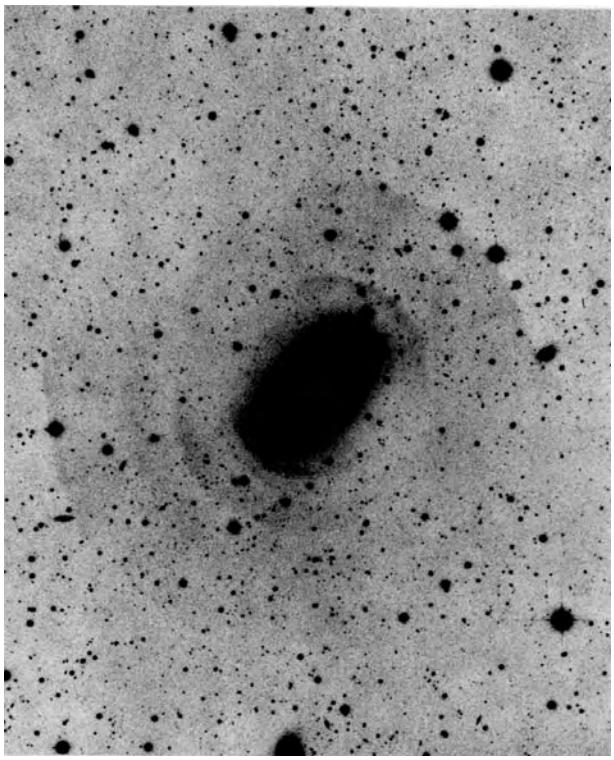

Figure 2. The spectacular shell system surrounding the elliptical galaxy NGC3923. Careful photographic processing, known as unsharp masking, first revealed this extensive set of shells which continues into the central region of the galaxy. Kinematics and intrinsic shapes

Measurements of the rotation and random motions of the stars in ellipticals are made from the shifts and width of absorption lines in the spectra of the galaxies along the major axis. The random motions are characterized by the value of the dispersion of the Gaussian that best fits the width of the absorption lines: the velocity dispersion, σ. Early measurements revealed that more luminous galaxies have broader lines such that the total luminosity $L \propto \sigma^4$. This is known as the Faber–Jackson relation after the first people to draw attention to this in 1975. This discovery ignited an interest in using measurements of galaxy velocity dispersions to estimate the intrinsic luminosity of ellipticals and thus determine their distances. This possibility stimulated researchers to make surveys of galaxy dispersions and these produced a much better understanding of the relationships between their structure, dynamics and stellar populations that will be discussed under 'Global properties'.

Until the late 1970s it was assumed that the flattened figures of elliptical galaxies arose because the stars in the equatorial plane are supported by their rotation about the galaxy minor axis. However, as soon as the rotation velocities of the most luminous elliptical galaxies could be measured it was discovered that they are too small to

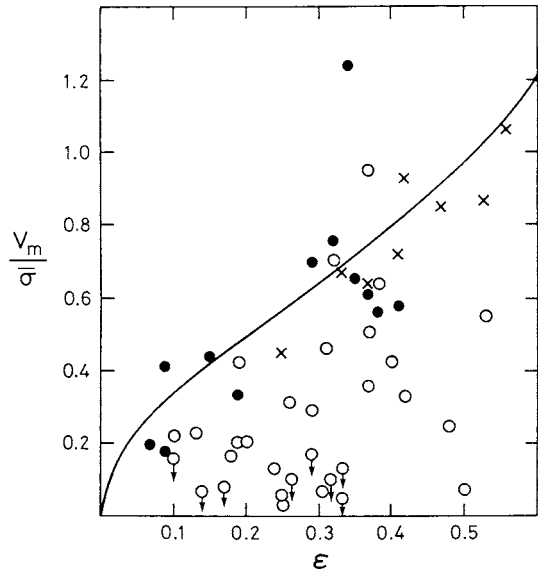

Figure 3. The maximum rotation velocity (V_m) normalized to the average velocity dispersion ($\bar{\sigma}$) plotted against apparent ellipticity (ε) for a sample of luminous ellipticals (open circles), faint ellipticals (full circles) and the bulges of spiral galaxies (crosses). The curve represents the expected relation between rotation and flattening for oblate galaxies with isotropic velocity dispersions that are supported by rotation. The bulges and faint ellipticals appear to conform to this model but the luminous ellipticals have significantly lower rotation velocities. Note that when galaxies are viewed edge-on the ellipticity is greatest and they are expected to have the highest rotation velocities; as they are viewed closer to pole-on they are seen to be rounder and V_m is also reduced. Thus if a galaxy is viewed at a range of inclinations to the line-of-sight it is expected to remain roughly on the predicted line. (Figure from Davies R L *et al* 1983 *Astrophys. J.* **266** 41.)

account for the observed flattened figures. Furthermore, when kinematic maps of ellipticals were made some dramatic examples of substantial rotation on the minor axis were found. This discovery led to a reassessment of the nature of elliptical galaxies. Figure 3 shows the rotation velocity, normalized to the central velocity dispersion, plotted against ellipticity for luminous elliptical galaxies, fainter ellipticals and the bulges of edge-on spiral galaxies. Also plotted is the expected relation for galaxies that are oblate and rotationally supported. Luminous elliptical galaxies are deficient in rotation by a large factor. Rotation is dynamically unimportant for luminous ellipticals; they are supported by the *random* motions of the stars. These random motions are not isotropic and this anisotropy produces the flattened figures observed. This discovery also challenged the assumption that ellipticals have oblate shapes and opened up the possibility that they could be prolate (two short axes equal, like a sausage) or even triaxial where all three axes have different lengths (like most potatoes).

We now believe that most luminous elliptical galaxies are triaxial and that the observed isophote twisting arises from the projection onto the sky of the changing intrinsic axial ratio with radius. This hypothesis also accounts for the rotation sometimes observed on the projected minor axis. This view has been established statistically from both the distribution of observed shapes of thousands of galaxies and from observations and models of the kinematics of many tens of galaxies. The average intrinsic shape for luminous elliptical galaxies is, however, poorly constrained. Most estimates are close to perfectly triaxial (where the intermediate length axis is the average of the long and short), e.g. a:b:c::1:0.85:0.7 with considerable scatter. These statistical studies suggest that intrinsically spherical galaxies are rare but, for example, cannot rule out a distribution of intrinsic shapes that is a mixture of oblate and prolate figures. The discovery that elliptical galaxies are not flattened by their rotation has important implications for our ideas about how they form. Models where isolated massive clouds of gas collapse dissipationally and form stars rapidly always produce galaxies which rotate faster than is observed. These results strengthened the view that elliptical galaxy formation proceeds through a sequence of mergers (of objects on misaligned orbits), to produce a galaxy with low total low angular momentum.

Figure 3 also shows that the less luminous elliptical galaxies and the bulges of spiral galaxies fall on or near the line describing isotropic oblate galaxies, showing that these objects have substantial kinematic similarities and are both qualitatively different from their more luminous brethren. Whereas luminous elliptical galaxies have complex kinematic structures, figure 3 shows that low-luminosity elliptical galaxies and the bulges of spiral galaxies have isotropic velocity dispersions and oblate figures flattened by rotation. There are many other characteristics of elliptical galaxies that vary with luminosity and that I will discuss in the section on 'Global properties'.

Anisotropy and mass-to-light ratio

Precise determination of the distribution of mass within elliptical galaxies requires detailed measurements of their luminosity profile and kinematics together with self-consistent dynamical models. Both analytic models based on the Jeans equations and models that construct galaxies by selecting orbits from a library (Schwarztschild's method) have been successfully used (STELLAR DYNAMICS). For luminous ellipticals infering the distribution of mass within a galaxy on the basis of these data and models is complicated by the degeneracy between changes in M/L, and changes in the orbital anisotropy of the stars. Using only measurements of the rotation and dispersion we cannot distinguish between an increase in M/L and an increase in one component of the velocity dispersion at the expense of another. Techniques based on measuring the *shape* of absorption line profiles have been developed to break this degeneracy. The shape of absorption lines is determined by the luminosity distribution and the number of stars at each velocity along the line of sight. In the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

center of a galaxy an increase in dispersion may indicate an increase in M/L *or* an increase in the fraction of radial orbits. The latter will, however, produce a line profile that is less sharply peaked than a Gaussian. Thus by measuring deviations from a Gaussian profile as well as its width we can determine whether stars are predominantly on tangential or radial orbits.

This ambiguity can be avoided altogether for low-luminosity ellipticals or spiral bulges as we believe them to have isotropic dispersions so determining the mass distributions in these systems is more straightforward. Similarly if galaxies possess disks of excited or ionized gas we can trace the mass distribution in the same way as for spiral galaxies.

A review of the topics covered in this section can be found in de Zeeuw and Franx (1992).

Dark haloes: mass at large radius

Spiral galaxy rotation curves have been used to show that they are embedded in dark haloes that contain three to ten times as much mass as is visible in stars, gas and dust. Can dark haloes be detected in elliptical galaxies? The velocity dispersion in many galaxies remains roughly constant (outside the central region) to one or more effective radii. As galaxies get rapidly fainter away from the center does this mean we are detecting a dark halo or is the fraction of stars on circular orbits increasing with radius? In the outer parts of a galaxy, if there are more stars on circular orbits the absorption lines will be less peaked than a Gaussian and have truncated wings. In a few elliptical galaxies where the measurements extend to two to three effective radii the line of sight velocity profile has been used to eliminate the possibility of tangential anisotropy and indicate the presence of a dark halo. Similar conclusions are drawn from the velocities of GLOBULAR CLUSTERS and PLANETARY NEBULAE at large radii in elliptical galaxies.

An important probe of the mass distribution at large radius is the hot x-ray emitting gas that has been detected out to five to ten effective radii in a large number of elliptical galaxies. This gas is enriched in heavy elements and is thought to originate from the stellar component of the galaxies through mass loss during the late stages of stellar evolution. By assuming that this gas is isothermal and in hydrostatic equilibrium it is possible to estimate the mass out to very large radii from the distribution of x-ray emission. These measurements have confirmed that elliptical galaxies reside in massive haloes qualitatively similar to those of spiral galaxies. With the advent of more capable x-ray satellites that can determine the temperature of the x-ray gas the simple assumptions required to estimate masses have been confirmed for a small number of galaxies.

Amongst the most luminous elliptical galaxies are those that possess an extended (compared with a de Vaucouleurs law) low surface brightness halo, known as 'D-type' galaxies, often found in the centers of rich clusters when they are classified morphologically as 'cD galaxies'. As well as high luminosity and extended halos these galaxies often have more than one nucleus, that is several smaller galaxies are superimposed on the image of the galaxy center. cD galaxies appear to be the product of many interactions or mergers of cluster galaxies with the central dominant galaxy. Several attempts have been made to measure the stellar kinematics in these out to large radii to establish the M/L at large radii and determine whether the stars in the halo are moving in the cluster potential. In a few such galaxies we observe the velocity dispersion rising with increasing radius; however, they do not reach the cluster dispersion, nor do they reach the velocity dispersion expected on the basis of the velocities of the multiple nuclei, so the interpretation of these motions remains controversial.

The centers of ellipticals

The center of a galaxy is a unique environment. The potential well is deepest at the center and any material that dissipates energy in collisions, such as dust or gas, will fall to the center relatively rapidly. For a giant galaxy this will take at most a few hundred million years. Galaxies of all types exhibit special phenomena at their centers. The high-resolution Hubble Space Telescope surveys of the centers of ellipticals often reveal patches or disks of dust and central stellar disks. The centers sometimes host powerful radio sources (see ACTIVE GALACTIC NUCLEI) or even star formation. We believe that radio galaxies are powered by massive black holes, and as a result the centers of elliptical galaxies have been identified as likely sites of black holes.

Black hole searches

Studies of quasars and galaxies at high redshift reveal that active nuclei were much more common at high redshift ($z \sim 2$), sufficiently common that we infer that most luminous present-day galaxies underwent an active phase and therefore should contain a massive central black hole. Searches for central black holes started in the late 1970s with observations of the luminous radio galaxy M87 (pictured in M87: THE MASSIVE GALAXY). From the rapidly increasing central velocity dispersion it was concluded that a black hole of 3 billion solar masses was present in the nucleus. The interpretation of these data was controversial because of the uncertainty introduced by the degeneracy between orbital anisotropy and mass distribution. These important observations stimulated a great deal of investigation of anisotropy and stability, new models were produced and more refined observations were made that increased our confidence in the case for a massive black hole in M87. In the 1990s measurements by the Hubble Space Telescope (HST) of the velocity of the excited gas close to the nucleus revealed a gradient in velocity of ± 500 km s^{-1} across the central 40 pc of the galaxy implying a mass of $2.4 \times 10^9 M_\odot$ contained within a radius of 20 pc. This provided strong confirmation of the black hole hypothesis independent of the uncertainties concerning the mix of stellar orbits.

The Hubble Space Telescope (HST) has carried out extensive imaging surveys of galactic nuclei finding many galaxies that have stellar cusps (luminosity profiles that continue to increase in surface brightness to the limit of resolution of the telescope). Other galaxies have been found with resolved cores where the luminosity profile reaches a constant brightness at a finite radius. These measurements are important for evaluating the value of any central mass but a nuclear cusp alone cannot be used to conclude that a black hole is present. When combined with kinematic measurements, made mostly from the ground, we have been able to address the more general question of the frequency of black holes in elliptical galactic nuclei. More than 20 galaxies have been studied in detail. A general trend has emerged: more massive galaxies host more massive black holes. The black hole has roughly 0.2–0.6% of the total galactic mass. This relationship is very uncertain and exhibits a factor of three scatter in the black hole mass, but if true it has wide-ranging implications (see ACTIVE GALAXIES: OBSERVATIONS). However, not all galaxies are *required* by the observations to host a black hole.

A good review of the evidence for supermassive black holes in galaxies of all kinds can be found in Kormendy and Richstone (1995).

Kinematically decoupled cores

As measurements of rotation velocities and velocity dispersions were made with greater resolution and precision an increasingly large number of galaxies were found to have central kinematics that were decoupled from those of the bulk of the galaxy. The most dramatic examples have the central region (typically 0.1–0.3R_e) rotating in the opposite direction from the rest of the galaxy, some have cores rotating about an axis less misaligned, in yet others the cores have very much higher rotation and lower velocity dispersion than the main galaxy. The latter suggests that there is a central disk embedded in the elliptical. These components often occur in the less luminous elliptical galaxies together with with disky isophotes and stellar cusps. In addition to these extended components the HST surveys of galactic cores have revealed many small (100 pc) disk components in ellipticals. Decoupled kinematics are not limited to ellipticals, one early-type DISK GALAXY has been found where two identical co-extensive disks rotate with the same velocity but in opposite directions!

Although at first such decoupled systems were considered rare, taking account of projection effects and the difficulty of detecting small or weak components we now believe that between one- and two-thirds of all elliptical galaxies have extensive central components with decoupled kinematics (i.e. that are a kiloparsec or so across and have been discovered from the ground). The most likely origin for the decoupled central components in ellipticals would appear to be through the accretion of material with different specific angular momentum from that of the main body of the galaxy. The existence of decoupled cores has been widely cited as evidence that elliptical galaxies have experienced significant accretions in the past; however, the colors, metallicity and age of the stellar populations appear to be indistinguishable from those of the main galaxy itself. We will return to the possible origin of these components in the final section.

Stellar populations

In the Milky Way we have used the concept of STELLAR POPULATIONS as an important tool in unraveling our Galaxy's history. We would like to extend these ideas to external galaxies. The colors and absorption line strengths measured in the spectra of the integrated light of elliptical galaxies are rather similar to those of the bulge of the Milky Way. Such considerations led us to believe that elliptical galaxies are old, single stellar populations devoid of star formation, which are now largely quiescent. The oldest stars in the Milky Way are found in the globular cluster population. Elliptical galaxies possess globular cluster populations in proportion to their luminosity (see GLOBULAR CLUSTERS) and the colors of these populations suggest that a substantial fraction of them are as old as the globular clusters in the Milky Way, i.e. the oldest stars in elliptical galaxies are as old as the oldest stars in our galaxy.

Even the nearest luminous elliptical galaxies cannot be resolved into individual stars from the ground, and only a handful can be resolved with HST so we are forced to try to unravel the integrated light from all the stars. By analysing the integrated spectrum we aim to discover what kind of stars constitute an elliptical galaxy. We approach this by using a library of stellar spectra or model stellar atmospheres covering a range of luminosity and effective temperature. We combine these using our knowledge of the relative numbers of stars in a population of a particular age and metallicity based on evolutionary models (see STELLAR EVOLUTION, STELLAR ATMOSPHERES). In this way we attempt to synthesize the observed integrated spectrum from known stellar components. In the optical ($\lambda = 0.5\ \mu$m) we find that about half the light arises from main sequence stars and half from giant stars but that ellipticals have an excess of light in the near infrared ($\lambda = 1$–$2\ \mu$m) and in the ultraviolet ($\lambda = 0.2\ \mu$m). The former can be attributed to stars with a higher metal content than the Sun, whereas the latter are likely to arise from extreme horizontal branch stars (see also HOT STELLAR POPULATIONS IN ELLIPTICAL GALAXIES). Both types are missing from the local stellar libraries.

We would like to infer the star formation history of ellipticals from their integrated spectra, but assigning a unique age and metallicity to an elliptical galaxy using this technique has proved remarkably troublesome. The result of increasing the age of the stars in the models is very similar to that of increasing their metallicity; both make the spectra redder and increase the strength of absorption lines. In recent years techniques using the strength of the hydrogen Balmer lines as age indicators have enabled separate age and metallicities to be determined and the initial applications of these methods suggest that elliptical

Dirac House, Temple Back, Bristol, BS1 6BE, UK

galaxies in rich clusters form a constant age sequence (say roughly 10 Gyr old) with metallicity varying from three times solar in the most luminous galaxies to one-third solar in those 100 times fainter. Samples of galaxies drawn from lower-density environments exhibit a much wider range in age, some having luminosity weighted ages as young as 2 Gyr! The symptoms of a young stellar population (<5 Gyr old) are easier to detect beacuse younger stars are much more luminous (per unit mass) than older stars so even a small mass fraction can significantly modify the integrated spectrum of an elliptical. These results suggest an environmental dependence on the star formation history of ellipticals such that galaxies in dense regions formed completely at early epochs whereas those in less dense environments have continued to experience star formation (perhaps involving only a small fraction of the total mass) until recent times. With the advent of HST and large ground-based telescopes it has become possible to observe galaxies at high redshift in sufficient detail to evaluate how they have changed over a considerable fraction of the age of the universe, and therefore measure galaxy evolution directly. I will discuss these powerful observations in the final section.

Global properties

Almost all the physical properties of elliptical galaxies vary smoothly with increasing luminosity. I have already discussed how the degree of rotational support decreases with increasing luminosity, a fundamental difference in the orbital make-up of faint and luminous ellipticals. This trend was only discovered through detailed study of the kinematics of tens of elliptical galaxies. While this work is becoming easier with the development of area spectrographs such as SAURON, many more galaxies have been characterized by single central spectra. These measurements have resulted in the discovery of a number of global relationships between properties that are easily measured for hundreds of galaxies. Remarkably there are tight correlations between parameters which are measured locally at the center of the galaxy, such as velocity dispersion, and global parameters such as size and brightness. I summarize these global relations here. They form much of the basis for our understanding of how elliptical galaxies formed and evolved.

The color–magnitude relation

The most luminous elliptical galaxies are slightly redder than the faintest ellipticals. This is a small effect but it has very small scatter (a few hundredths of a magnitude) and is well established in nearby clusters of galaxies. There has been a debate over the origin of this effect, is it due to a higher average metal content in the luminous galaxies or are they on average older? The color–magnitude relation has been observed as a tight correlation in clusters at redshifts in excess of 0.5 and this makes the interpretation in terms of age changes unlikely. This result is established in clusters, the simplest assumption to make is that the color–magnitude relation is universal, but this is not yet proven. We believe that the color–magnitude effect arises because the deeper potential wells of luminous galaxies can retain the metals produced in supernova explosions more effectively.

The Mg–σ relation

This correlation involves the strength of the magnesium absorption features at a wavelength of 0.52 μm and the stellar velocity dispersion σ. Galaxies with high-velocity dispersions have stronger magnesium absorption lines. (This is the best developed correlation but other absorption line strengths have also been used.) This relation also exhibits very little scatter, <0.02 magnitudes, and because it is a distance-independent correlation galaxies from a wider range of environments can be included. Once again the correlation could arise from changes in age or metallicity, but measurements in rich clusters out to $z = 0.4$ are consistent with the local relation changed only through the stellar evolution that occurs in that time interval (about 4 Gyr). This suggests that the correlation arises because high-σ galaxies are metal rich. Tests of this relation in different galactic environments have failed to find any systematic differences.

The Faber–Jackson relation and the Fundamental Plane

Earlier I introduced the Faber–Jackson relation: the increase in central velocity dispersion with luminosity, $L \propto \sigma^4$. In the 1980s surveys of elliptical galaxies were made to measure the non-Hubble motions of galaxies. Using the high-quality data collected it became apparent that an extra parameter, the galaxy surface brightness, increased the precision of the L, σ^4 relation as a distance indicator. Thus a new relationship, which has become known as 'the Fundamental Plane' superceded the L, σ^4 relation. The Fundamental Plane relation is:

$$\log R_e = 1.25 \log \sigma + 0.33 \langle SB_e \rangle + \text{constant}.$$

where SB_e is the effective surface brightness I_e expressed in magnitudes and $\langle SB_e \rangle$ is the average surface brightness within R_e so that $\langle SB_e \rangle = 3.61 SB_e$.

In the size, velocity dispersion, surface brightness space elliptical galaxies are not distributed uniformly, they fall on the above plane with relatively small intrinsic scatter of about 15% in R_e. The Fundamental Plane (FP) is close to what would be expected on the basis of the virial theorem if all galaxies have the same M/L ratio. The difference with the observed relation can be used to restrict the possible range in M/L of ellipticals to a factor of three. Similarly, the width of the plane can be used to restrict the scatter in M/L at any point in the plane to be less than 12%.

The scatter in the FP and the Mg–σ relations are sensitive to the range in *both* the age and metallicity of the stellar population. However, the scatter in the FP is more sensitive to the range of ages, whereas the scatter in the Mg–σ relation is more sensitive to the range of metallicities. Using these two together the range in the age and metallicity of ellipticals has been restricted to 30%,

i.e. luminous ellipticals vary from say 10–13 billion years old and have metallicities in the range 3 ± 1 times solar abundance.

Structural properties
Many structural properties vary smoothly with luminosity or central velocity dispersion. I have discussed most of them already but bring them together here. Statistically, large, luminous, high-velocity dispersion elliptical galaxies have higher x-ray luminosity, host more powerful radio sources, have triaxial figures and anisotropic velocity distributions and have boxy isophotes and flat central luminosity profiles. Alternatively the small, low-luminosity ellipticals and spiral bulges have lower x-ray and radio luminosities, have oblate figures and isotropic velocity distributions, and have disky isophotes and cuspy central luminosity profiles. These differences have been used to argue that luminous-boxy and faint-disky galaxies formed and evolved differently and should be part of separate morphological sequences. This hypothesis is attractive but has yet to address how two physically distinct classes obey the same color–magnitude, FP and Mg–σ relations if indeed careful study proves that they do.

The morphology–density relation
Elliptical galaxies are gregarious, they are most often found in regions of high galaxy density. The mix of galactic morphological types is a strong function of environment, in rich clusters approximately 40% of the galaxies are ellipticals and another 50% are lenticulars with the remaining 10% being spiral galaxies. In less dense environments the fraction of ellipticals falls dramatically while the spiral fraction increases. In the lowest density environments less than 10% of galaxies are classified as elliptical with spiral and lenticular galaxies being found in roughly equal proportions. The same analysis has been carried out for clusters of galaxies at $z \sim 0.4$ imaged by the HST. The ellipticals still dominate the galaxy population in rich clusters at $z \sim 0.4$ but the fraction of lenticular galaxies has dropped to 20%, with spirals accounting for 30% of the rich cluster population. It is clear that in rich clusters the elliptical galaxy population is already in place by $z \sim 0.4$ but that there are very many fewer early type galaxies with disks than we find in rich clusters today.

How and when did elliptical galaxies form?

We believe that the distribution of galaxies traces out the large-scale structure of dark matter and that the dark matter haloes of galaxies assemble hierarchically with the most massive haloes forming most recently. Only through understanding the behavior of the baryons within these haloes can we hope to understand how the luminous galaxies we observe evolve.

The high central densities and relaxed structure of elliptical galaxies are taken as strong evidence that they underwent substantial gaseous dissipation during formation. Furthermore the small scatter observed in their global relations suggests that they are old (with a formation redshift greater than $z = 2$–3) and coeval. These considerations have led to models in which elliptical galaxies form through the dissipative collapse of a massive gas cloud resulting in a huge starburst which turns almost all the gas in a halo into stars simultaneously, say 10 billion years ago. The most recent measurements at sub-millimeter wavelengths have detected galactic masses of cool dust at $z = 2$–3 that are forming stars at a very high rate. These sub-millimeter sources have been identified as the progenitors of the most luminous cluster ellipticals we see today. However, models show that the monolithic collapse of a massive gas cloud produces an unrealistically rapid rotation in the end product and furthermore the collapse of massive objects at high redshift appears to contradict the hierarchical assembly of galaxies.

These drawbacks have led to alternative suggestions that ellipical galaxies formed through a sequence of galactic mergers. There is much empirical evidence for this: low rotation velocities, decoupled cores and shells are all a natural consequence of accretions and mergers. In the alternative model disk galaxies merge together to generate elliptical galaxies during the formation of groups and clusters of galaxies. Theoretical investigations of galaxy mergers using n-body techniques have successfully demonstrated that disk galaxies undergoing mergers will produce elliptical galaxies with de Vaucouleurs' law luminosity profiles and low rotation velocities. In cosmological simulations the bulk of the stars that comprise present day ellipticals form in merger events that occur typically at $z = 1$–2. The galaxies continue to grow in mass and luminosity through mergers until they fall into massive clusters where the typical velocities of galaxies get so large that mergers are inhibited. This scenario accounts for why ellipticals are predominantly found in high-density regions and predicts that on average ellipticals in rich clusters will be older (in the sense of a luminosity weighted age) than those in less dense regions.

These two formation mechanisms predict different age distributions of elliptical galaxies, particularly as a function of galactic environment. We would like to infer the star formation history of ellipticals from their integrated spectra, in particular to distinguish between the hypotheses that the stars formed in a single event at high redshift, $z > 2 - 3$ or that star formation was much more extended with perhaps some star formation occurring at $z \ll 1$. Such tests are under way. It has been suggested that the two flavors of elliptical galaxy, luminous-boxy and faint-disky, may have different evolutionary histories with luminous-boxy galaxies formed predominantly through a dissipationless merging sequence that produce triaxial anisotropic galaxies. The luminosity weighted ages of the two flavors of ellipticals have yet to be determined.

The powerful telescopes at our disposal now, in particular the HST, have enabled us to study the evolution of elliptical galaxies directly. We have known for more than two decades that the fraction of blue galaxies in rich clusters at high redshift ($z = 0.5$) is much higher than

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

we find in local clusters. HST has revealed this blue excess as disk galaxies and has established that at $z = 0.5$ elliptical galaxies have already assembled. It seems very likely that these massive cluster ellipticals did form rapidly and early at $z > 3$ and they ceased star formation before $z = 1$. Perhaps ellipticals in lower-density environments will be found to have experienced a more extended and recent series of mergers, giving them younger mean ages. Such a formation scenario takes ingredients from both the monolithic collapse and merger hypotheses for the origin of ellipticals but already faces apparent contradictions with the empirical measurements.

Bibliography

An excellent general text on the Milky Way and other galaxies is

Binney J J and Merrifield M 1998 *Galactic Astronomy* (Princeton, NJ: Princeton University Press)

In particular chapters 4, 5 and 11 cover material on the morphology, stellar population and kinematics of elliptical galaxies.

The dynamics of elliptical and bulges is reviewed comprehensively in

de Zeeuw P T and Franx M 1992 *Ann. Rev. Astron. Astrophys.* **29** 239

An excellent overview of the searches for black holes in galactic nuclei can be found in

Kormendy J and Richstone D 1995 *Ann. Rev. Astron. Astrophys.* **33** 581

A more advanced treatment of galaxy dynamics which includes many of the topics introduced here can be found in

Elongation

In general use, the angular separation between the Sun and a planet (or other body orbiting the Sun) or the Moon, i.e. the angle Sun–Earth–object. A more accurate definition, which takes account of the fact that the orbits of bodies orbiting the Sun are inclined to the plane of the ecliptic (the Earth's orbital plane), is that the elongation of a body is the difference between its celestial longitude and the Sun's. Elongation is measured in degrees east or west of the Sun. If a body's elongation is 0° it is at conjunction, if 90° it is at quadrature, and if 180° it is at opposition. The term is also used for the angular separation between a planet and one of its satellites, i.e. the angle planet–Earth–satellite, measured east or west of the planet.

The elongations of the inferior planets, Mercury and Venus, are restricted between certain limits. These maximum angular separations from the Sun are termed *greatest elongation east*, when the planet sets at the latest time after the Sun at a particular apparition, and *greatest elongation west*, when it rises at the earliest time before the Sun at a particular apparition. In Mercury's case, greatest elongation varies between $17^\circ\ 50'$ when the planet is at perihelion (closest physical distance to the Sun) and $27^\circ\ 50'$ when it is at aphelion (farthest from the Sun). For Venus, which has a much less eccentric orbit, greatest elongation varies between 45° and 47°.

Emission Spectrum

A spectrum that consists of a number of bright emission lines, each line corresponding to the emission of light at a certain particular wavelength. An atom or ion will emit a photon of a particular energy (and hence of a particular wavelength) when one of its constituent electrons spontaneously drops down from one of its higher ('excited') permitted energy levels to a lower energy level (i.e. when the electron makes a 'downward transition'). The various permitted transitions correspond to a series of lines of different wavelengths, the wavelength of each line being inversely proportional to the magnitude of the energy gap between the relevant energy levels. In addition to undergoing electronic transitions (like atoms and ions) molecules may also emit radiation at characteristic wavelengths through downward transitions in their vibrational and rotational states.

In order to emit radiation through downward transitions, atoms, ions and molecules must first be excited to higher energy levels. This may occur through radiative excitation (absorbing incoming photons) or through energetic collisions between atoms, ions or molecules. Emission will also occur when an ion captures an electron (this process is usually called 'recombination'). Usually, an electron will be captured into an excited level of the atom or ion and will then drop down to lower levels in a series of steps, each of which corresponds to the emission of light of one particular wavelength. When an electron is captured, the difference between the energy that it possessed before being captured, and its energy that is has when bound to the atom or ion, is radiated away. Depending on the range of energies of the free electrons that are available to be captured, the series of lines in an emission spectrum may end in an emission continuum (emission over a continuous range of wavelengths shorter than that of the shortest-wavelength individual line).

An emission spectrum is characteristic of a high-temperature, low-density gas. Typical sources of emission spectra include fluorescent strip lights, the chromospheres and coronae of stars, luminous nebulae, active galactic nuclei and quasars.

Empedocles of Akragas (*c*. 492–*c*. 432 BC)

Lived in Acragas (now Agrigento, Sicily), as the author of a physical-cosmological poem entitled *On Nature*, which developed the ideas of the Miletian philosophers like XENOPHANES who believed that the different forms of matter are manifestations of basic elements in different mixtures. Xenophanes suggested that everything was composed of two elements, water and earth, and Empedocles extended this to four: earth, water, air and fire. He believed that the Sun was a reflection of fire, and is credited as the originator of the concept that light has a finite velocity.

Enceladus

A mid-sized icy satellite of Saturn, discovered in 1789 by William Herschel. Its diameter is 500 km and it orbits Saturn at a distance of 238 000 km. The part of Enceladus imaged in the Voyager mission has two distinct types of terrain: areas with a medium density of cratering, and almost crater-free plains with extensive fault features—straight and curved grooves and ridges, such as Daryabar Fossa and Samarkand Sulci. The satellite possesses an albedo of 1.0, the highest known, which suggests that its surface is very fresh. So, not only has Enceladus been geologically active in the past, it may still be so today. Its bulk density is 1120 kg m^{-3}, indicating a largely water-ice composition. The activity is made possible by the formation of what is known as a eutectic melt of ammonia and water which is molten at a temperature as low as 176 K. The energy for the activity could be supplied by tidal heating, produced by the satellite's slightly elliptical orbit and a 2 : 1 orbital resonance with Dione. Enceladus orbits at the center of Saturn's tenuous E ring; meteoric debris from the satellite is believed to be the source of the ring's small particles.

Encke, Johann Franz (1791–1865)

Astronomer, born in Hamburg, became professor and director of the observatory at Berlin. Discovered a comet in 1805, which he later found to be identical with a comet observed in 1818. *Encke's Comet* has a period of 3.3 years (the shortest of any comet), and Encke predicted its return for 1822 (seen only in the southern hemisphere) and in 1825 (which Encke observed from the Seeberg Observatory near Gotha). Presided at the Berlin Observatory over work on calculation of the orbits of asteroids, and the discovery of Neptune by GALLE with the help of star charts that Encke had edited. In 1838, discovered the gap between the A- and F-ring around the planet Saturn (now known as the *Encke division*).

Energy

A physical quantity that, traditionally, is defined to be the ability to do work, where 'work' is the application of a force over a distance. The energy that a body possesses by virtue of its motion is called kinetic energy, the kinetic energy (KE) of a body of mass m traveling at velocity v being given by: $\mathrm{KE} = 1/2mv^2$. In order to change the velocity of a body, a force must be applied, the resultant change in the kinetic energy of the body being equal to the work done by the force. The energy that a body possesses by virtue of its location is called potential energy. When a body of mass m is raised to a height h the potential energy (PE) that it gains is given by: $\mathrm{PE} = mgh$, where g is the acceleration due to gravity (this particular expression assumes a constant gravitational field; in practice, the gravitational attraction exerted on the body decreases with increasing height). Potential and kinetic energy are interchangeable. If the body is released from height h, it will accelerate towards the ground, so converting its potential energy into kinetic energy.

Energy exists in a wide variety of forms. For example, heat is essentially the kinetic energy contained in the motions of atoms, molecules, or ions. Electromagnetic radiation is a form of energy, the energy of a photon (a 'particle' of electromagnetic radiation) being inversely proportional to the wavelength of the radiation. According to the special theory of relativity, energy (E) and mass (m) are equivalent and interchangeable, the relationship between the two being given by $E = mc^2$, where c denotes the speed of light. Because c is a large number, a small mass is equivalent to a very large quantity of energy. The conversion of mass to energy through nuclear reactions powers the stars. The law of conservation of mass-energy states that the total amount of mass-energy in an isolated system is constant (one form can change into the other, but the total sum of mass and energy remains the same).

The SI unit of energy is the joule (J). A unit that is commonly used in particle physics is the electronvolt (eV).

Environmental Threat to Astronomy

Astronomy is fortunate in being one of those sciences currently making important advances in understanding, well supported by superb, advanced, technology. Revolutionary new data are being acquired which are radically impacting upon our cherished concepts from the solar system to the depths of the universe. Sadly, the state of astronomy at the dawn of the twenty-first century is not one of unbounded optimism, for the very technology which has produced the current, unparalleled, scientific advances is also capable of inflicting catastrophic damage on observational astronomy—the lifeblood of astronomical science.

Observational astronomy is concerned with detecting extremely weak electromagnetic radiation emitted by cosmic objects. The limiting strength that can be observed is determined by the strength of the background noise against which the radiation is detected. Natural backgrounds are weak (except in the case of the infrared) and therefore small enhancements of natural background levels will significantly raise the level of detection of the faintest objects. Large backgrounds will be disastrous for all serious astronomical research. The activities of mankind produce large increases in astronomical backgrounds in many different ways.

Electromagnetic pollution

Electromagnetic pollution at radio wavelengths

The average mobile telephone, if at the distance of the Moon, has sufficient power output to be among the brightest radio astronomical objects. RADIO TELESCOPES suffer a cascade of radio signals generated on the ground and in space. These signals come from as simple a thing as flicking an on/off switch, through electrical machinery in its myriad forms to telecommunications transmissions and signals from position-fixing satellites. Many of these signals are weak, but any form of communications transmission is powerful (multimegawatts). Because of the nature of radio telescopes, they can pick up signals originating from directions other than that at which the telescope is pointed because of side lobe responses. Such side lobe responses can swamp the observed cosmic signal. Radio observatories can be partially protected from transmissions generated terrestrially by retreat to remote valleys well protected by mountains, but there is no protection at all from aircraft transmissions or transmissions from orbiting satellites. The exploitation of space for telecommunications purposes is growing explosively with the launch of satellite clusters such as Iridium. Despite the careful regulation of radio-frequency space by the International Telecommunications Union, residual noise at significant levels enters the bands reserved for RADIO ASTRONOMY and other passive services (not-transmitting) from neighbouring bands used commercially, through insufficiently attenuated signal tails or signal harmonic frequencies or inadvertent (and sometimes deliberate) tuning through or into the reserved radio astronomy bands. Despite ingenious procedures developed by radio astronomers, such noise frequently degrades, and often swamps, the cosmic signals being observed

Figure 1. Light pollution at Stonehenge. Light pollution looking north-east at Stonehenge (UK), 2 October 1996. Stonehenge is in a rural area! (Copyright D McNally.)

Electromagnetic pollution at optical wavelengths

Optical wavelength electromagnetic pollution is particularly simple to demonstrate. It is clearly visible (see figure 1). The growth of outdoor lighting installations over the last 50 years has produced a high level of background illumination in cities, towns and urban areas which spills a considerably way into rural areas. The light spill from one urban area may overlap the light spill from neighboring urban areas. In the UK there are few areas left where the background is the naturally occurring night sky glow—the essential limiting factor for astronomical observation. The pollution results from the fact that most luminaires now in use have significant upward light spill. It is possible for modern luminaires to have no upward light spill and have sufficient sideways cut-off to put the light emitted where it is needed. The requirement to cut energy consumption to reduce release of CO_2 into the atmosphere is forcing the pace of outdoor lighting design. It is now possible to light motorways and roads, outdoor playing fields, items of architectural note etc in such a way that the luminaires emit no lights upwards and the illumination is confined laterally to the area required to be illuminated—the light spill from these high-grade schemes is confined to the light reflected from the surface of the ground and such light scattered by atmospheric particulates (see later). Unhappily such high-quality designs are the exception rather than the norm.

Because outdoor lighting is so necessary to twenty-first-century lifestyles, outdoor lighting is globally distributed. This means that not only are observatories established more than 50 years ago engulfed in overly lit urban areas, but even the remoter prime observatory sites are seeing growth in local outdoor lighting. As telescope diameters increase and detectors become more sensitive, so more observation is directed towards

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

objects who faintness approaches the natural background. Astronomers have argued that outdoor lighting should not increases the background by more than 10% of the natural background. Even that excess is not acceptable to those studying contributions to the natural sky glow. Most urban backgrounds exceed the natural background by at least a factor 100 and in the centres of major cities by factors of in excess of a million. This has a serious effect on optical observational astronomy.

Astronomers are also concerned about the spectral character of the lamps used in outdoor lighting. The low-pressure sodium lamp emits virtually all its output over a very narrow wavelength range—it is almost monochromatic. Clearly this lamp is preferred by the astronomical community. It is a highly energy efficient lamp. It is not universally liked as it gives poor rendering of color. However, addition of small amounts of white light at locations where color rendering is important can be very effective. Nevertheless there is pressure to use multispectral lamps (e.g. high-pressure sodium, halide) and the recent trend towards such lamps will progressively prevent astronomical use of some spectral ranges—whereas now only a very short spectral range occupied by low-pressure sodium lamps is unusable.

While OPTICAL ASTRONOMY, unlike radio astronomy, has trends working to its benefit, there is no escaping the fact that the background at optical wavelengths is increasing as are projects near prime observatory sites which demand high-intensity outdoor lighting (e.g. a new prison project is planned on Hawaii near the prime observatory sites on Mauna Kea which houses, *inter alia*, the world's two largest telescopes).

Exploitation of space

Exploitation of space has brought additional degradation of astronomical observing conditions over and above the effect on radio astronomy mentioned above. The use of space has meant the accumulation of space debris. There are now over 8200 pieces of trackable debris (size over 10 cm in low Earth orbit) in space and substantially greater amounts of smaller debris which can cause significant damage to operational spacecraft. Debris is now posing a threat to all operational satellites including orbiting astronomical observatories like the HUBBLE SPACE TELESCOPE.

The number of operational and spent satellites and large pieces of debris is so great that many astronomical deep sky images now carry trails caused by sunlight reflected by this subset of space debris. Fifty per cent of deep sky images carry at least one trail and 25% carry multiple trails. Such trailing also affects the very much smaller sized photometric fields of view. Since most of the trailing occurs within the 2 h after sunset, or before sunrise, the astronomical community lives with the image degradation or curtailment of the efficiency of operation that trailing causes.

Of more concern are proposals to place solar reflectors in space to produce the appearance of objects up to the brightness of 100 times that of the full Moon. The Moon is sufficiently bright to suspend astronomical observation of the faintest celestial objects for two weeks out of every four. Currently tests of the Znamya2 and Znamya2.5 solar reflectors have been attempted, but the tests could not be fully implemented. Were this technology to be proved, the astronomical nightmare is, that despite being only operational in twilight, such reflectors might be used for commercial or other advertising. Thus far, proposals for advertising reflectors have been turned down by the space agencies. But one is prompted to ask, should advertising from space become acceptable, would not advertisers then want systems in space which could exploit dark time (indeed there has been a suggestion for advertising holograms to be generated in space in dark time)? Were that to become the case, optical astronomy would die.

There is one proposal for the use of space reflectors which is of great concern—namely to use a system of such reflectors to collect enough solar energy to generate up to 50% of the world's demand for electricity by 2050. Solar radiation would be converted in space to microwaves for transmission to Earth where the microwave energy would be converted to electricity. The efficiency of the process is said to be less than 10%. What happens to the remaining 90% lost in the process? It is admitted that such a proposal would have serious consequences for ground-based optical astronomy and would be disastrous for ground-based radio astronomy. Such extension of the exploitation of space is of very great concern to the astronomical community.

Others areas of concern

Atmospheric extinction. The atmosphere contains naturally occurring particulates and aerosols augmented by those generated by the activities of mankind through dumping of industrial effluent into the atmosphere, emissions from vehicles, creation of dust etc. As pointed out in earlier, atmospheric particulates increase the scattering of outdoor lighting. Atmospheric extinction also decreases the energy received from cosmic sources as well as reddening that light. Increase in extinction is largely an urban phenomenon and relatively local except in the case of aircraft contrails. Generation of extinction in the northern hemisphere seems not to be spreading in the southern hemisphere, as yet. This is a problem requiring vigilance and study in case a serious problem is developing—particularly in regard to the consequences of aircraft contrails.

Accumulation of heavy molecules in the stratosphere. Infrared observers have found that the accumulation of heavy molecules in the stratosphere is increasing the extinction in the limited atmospheric windows available to ground-based infrared observatories. While some of these molecules are now banned (to prevent further damage to the ozone layer) it is not yet clear if replacement molecules will lead to any improvement for INFRARED ASTRONOMY. This is again an area for sustained vigilance.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Global warming and atmospheric heat dumping. It is agreed that the Earth's atmosphere is in a warming phase (see GREENHOUSE EFFECT). A consequence of rising temperatures is enhanced cloudiness—a trend reinforced by contrail formation in the absence of rapid dispersal (see earlier). Global warming may lead to changes in weather patterns, one consequence of which could be climatic degradation at prime observatory sites. As a corollary, in urban areas there is atmospheric dumping of heat from industrial processes down to heat loss from buildings. One clear consequence of such local and largely urban, heating is enhanced atmospheric turbulence and consequent degrading of astronomical SEEING.

Ground vibration. Industrial operations and other activities of mankind produce vibration. Vibration is a local phenomenon, but low-amplitude vibrational effects can be felt at distances of up to 10 km from source. This can be a serious problem for astrometric observatories in particular. Observatories free from vibration in the past may become susceptible because of new industrial development in the local neighborhood.

Other concerns. The above listing of areas of concern is not exhaustive. New concerns will appear and old concerns develop unforeseen and more serious consequences. There are still concerns regarding space activities that could result in terrestrial pollution of the nearby solar system bodies—which may affect the integrity of future exploration of those bodies. There is concern about the consequences of HAPS (High Altitude Platform Systems) on both radio and optical astronomy. There is concern in optical astronomy about the consequences of using optical/IR laser beams (e.g. ESA's SPOT4) for satellite communications. There will no doubt be many other concerns downstream. Astronomy is in consequence a highly beleagured science.

Protection measures

The science of astronomy has taken steps to protect itself. Despite many well equipped observatories on urban sites, the trend has always been for observatory sites to retreat ever further from centers of population (see OBSERVATORIES AND THEIR LOCATION). However, there is now no scope for further retreat except possibly through greater use of Antarctica. Space is not the user friendly, if costly, place it once seemed. Astronomers have therefore entered into local agreements to give special protection to prime observatory sites. So far these agreements have worked well, but it must be remembered that those living close to such sites may find these agreements overly restrictive in the future. Radio astronomers have been in detailed negotiation, nationally and internationally (through IUCAF, the InterUnion Committee on Allocation of Frequencies), with the International Telecommunications Union on allocation and defence of the radio astronomy bandwidth allocation. This has been extremely successful but is becoming a highly demanding business given the hunger commercially for bandwidth. These activities deserve the strongest community backing.

Astronomers have taken their concerns to the public. Light pollution is a topic which the public can readily appreciate and indeed emphathize with. Many people resent that they can no longer see the spectacle of a dark night sky. But it is hard to convey the dire situation faced by radio astronomy, though opposition to space reflectors seems to command global support.

In July 1999, the astronomical community had an opportunity to present their concerns to the UN at a symposium at UNISPACE III. The UN have taken on board for consideration astronomical concerns above the impact of exploitation of space and the problem that telecommunications pose for radio astronomy. Such consideration must of its nature be long term. One consequence will be that the astronomical community will have to commit significant resources to quantitative assessment of its observing environment. This will be essential in obtaining any future international agreement to protect astronomical science.

The astronomical community will also have to give greater attention to public information. Considerable effort is now expended and has demonstrably paid off. We still need to reach a wider audience since there is wide public interest in, and sympathy for, astronomical observation but it is coupled with widespread ignorance of how the activities of mankind impact upon astronomy. The outlook may well be bleak but it is not without considerable hope.

Ephemerides

In everyday language, 'ephemeris' indicates what occurs daily; the ephemeris of the day is the list of the remarkable events of this day. By extension, the astronomical ephemerides are tabular listings of the positions of a celestial body, allowing one to know its position for a given time. Today, ephemerides may have a new form in order to improve the accuracy of the positions deduced from them. Ephemerides provide representations of the motion of celestial bodies.

The ephemerides of positions are thus the representation of a motion. The most common ephemerides are those in the form of tables of numbers. But it is not the only possible form and, nowadays, it is no longer the best form because there are much more powerful ways to describe a motion. The quality of an ephemeris for the representation of a motion depends on two factors: the use of a small number of data (to avoid too large tables) and the possibility of good precision (to give the weakest error compared to the 'true' position).

Before discussing the various types of representation used for the ephemerides, let us see first of all how the motions of celestial bodies belonging to the solar system are described. One will see hereafter that the ephemeris itself depends on the nature of the motion which is to be described.

Planetary theories and ephemerides

History

Ephemerides have been published since the fourteenth century. The first ephemerides intended for use in planetary dynamics appeared in the French *Connaissance des Temps*, first volume of which was published in Paris in 1679. This first volume provided a tool for reducing the observations of solar system bodies. It contained rise and set times for the Sun, Moon, Mercury, Venus, Mars, Jupiter and Saturn, their transits to the Paris meridian, their longitudes, their latitudes and their declinations. Later, Lalande compiled the tables of the Sun and the planets which were used as a basis for the ephemerides published in the *Connaissance des Temps* until 1808. In 1767, an ephemeris of the same kind designed for the improvement of Astronomy, Geography and Navigation was published in London: the *Nautical Almanac and Astronomical Ephemeris*.

During the years 1770–1825, Laplace studied the consequences of the application of Newton's law of gravitation on the motion of the bodies of the solar system and solved several problems concerning planetary theories. The representation of these motions in the ephemerides evolved continuously, but until the end of the eighteenth century, the *Connaissance des Temps* presented the ephemerides month by month, the Sun day by day and the planets six days by six days. The time interval evolved (decreased) in order to improve the accuracy of the positions, day by day or more, depending on the motion of the body. From 1838, the ephemerides were published body by body. They were daily for the Sun, three days by three days for Mercury, six days by six days for Venus and Mars, eight days by eight days for Jupiter, ten days by ten days for Saturn and fifteen days by fifteen days for Uranus. For the Moon, a smaller interval was necessary (cf table 1). In 1863, the ephemerides were provided daily for Mercury, Venus, Mars, Jupiter and Saturn and four days by four days for Uranus and Neptune.

N

The development of celestial mechanics

The nineteenth century was very rich in progress in celestial mechanics and the motion of the solar system's bodies became well modeled (see CELESTIAL MECHANICS IN THE EIGHTEENTH AND NINETEENTH CENTURIES): it is even thanks to the defects noted on the ephemerides of Uranus that Neptune was discovered through calculations by Le Verrier and Adams. These defects did not result from a bad evaluation of the perturbations from Jupiter and Saturn: it was necessary to admit the existence of an additional body beyond Uranus. After the discovery of Neptune by Galle in Berlin, observations were realized and the elements of

the motion of Neptune were then known enough so that precise ephemerides could be published.

After such an achievement of celestial mechanics, Le Verrier undertook to completely rebuild the theories of the motion of the main planets. He derived the theories and the tables of these bodies. Gaillot, a collaborator of Le Verrier, then improved the theories of the four large planets, Jupiter, Saturn, Uranus and Neptune. At the same time, the theoretical work of Hansen gave rise to the Russian astronomer Kowalski's theory of Neptune and, especially, to Newcomb's global theory of planets.

The tables of Le Verrier and Gaillot were used in the ephemerides of the *Connaissance des Temps* until 1984 but the tables of Kowalski and those of Newcomb were the sources of the ephemerides of Neptune published in the *Connaissance des Temps* from 1863 to 1883. For Uranus, the tables of Newcomb were used from 1877 to 1883. *The Nautical Almanac* also used Le Verrier's tables; the American Ephemeris used Hansen's work and Newcomb's tables for the Sun and the planets, the tables of Hansen and Brown for the Moon, until 1983. In 1960, the British and the American ephemerides published the same tables, the name of which became *The Astronomical Almanac* in 1981.

At the time of Le Verrier and Gaillot, the ephemerides published in the *Connaissance des Temps* acquired a form which was used continuously until 1979 (cf table 2). Note that in 1877 the rectangular coordinates of the Sun were introduced and the ephemerides of Uranus and Neptune were provided daily in the *Connaissance des Temps*.

Ephemerides nowadays

Significant transformations have been made to the ephemerides in the last few years. In 1980, the tabular presentation of the ephemerides of the *Connaissance des Temps* was replaced by a representation in Chebyshev polynomials (see later); much more compact and well adapted to the development of microcomputers (cf table 3). Tables 1, 2 and 3 show the progress in the representation of the ephemerides of the Moon.

Since 1984, the *Connaissance des Temps* has used new analytical theories of the motions of the Sun, the Moon and the planets, elaborated at the Bureau des Longitudes and adjusted on the numerical integration of the Jet Propulsion Laboratory (JPL) DE200. In 1984, the *Astronomical Almanac* changed the sources of its ephemerides and used the numerical integration DE200/LE200 of the JPL. JPL is now using an improved ephemeris DE405/LE405. Theories and numerical integration will be described further.

Theories of the motions

Since the beginnings of astronomy, modeling the motion of the bodies of the solar system has been a challenge. First, these motions were empirical extrapolations of the observations carried out; the first tables thus came from a purely kinematic analysis of the observed motions. The precision of these first tables was obviously poor and could be increased only with the improvement of the precision of the observations themselves.

Then came calculations based on gravitational theories in which the parameters were deduced from observations. Since Newton, the dynamic laws were known and it was then important to include these in the equation and to take into account all the gravitational effects which have some influence on the bodies. Lagrange's theoretical search relative to the planetary problem resulted in modeling the long-term evolution of the orbits by a linear differential system which coupled the eccentricities and the inclinations. This result is fundamental.

Ephemerides may be made from theoretical equations by solving the equations into trigonometric series, which are time consuming to calculate without computers. Another way is the direct calculation through numerical integration.

Elements of celestial mechanics

General remarks on planetary theories

The motion of planets around the Sun is a particular case of the *N*-BODY PROBLEM which has no exact solution for *N* larger than 2. All the bodies attract each other in accordance with the law of gravitation but it is considered that the planets have a small mass relative to the one of the central body (the Sun). Approximate solutions of the problem have to be made thanks to the theory of perturbations, where the coordinates are functions of the time t, of the masses of the involved bodies and of the constants of integration. One obtains these solutions by deriving analytical theories or by carrying out numerical integrations.

Analytical theories

The coordinates are obtained in the form of combinations of analytical algebraic and trigonometrical functions of the time t and the parameters of the problem, masses and constants of integration. The calculation of a position using these theories is long but simple since it is sufficient to substitute the time parameter in the series.

Numerical integrations

Numerical integrations give the numerical values of the coordinates and velocities for some values t_0, $t_0 + h$, $t_0 + 2h$, etc, t_0 being the initial time and h being the step of integration. The methods of numerical integration are well adapted to calculations by computer and they were especially used at the Jet Propulsion Laboratory in the USA.

The time argument of the ephemerides

It is advisable to now say some words on the 'time' argument of the ephemerides. Indeed, to know a position at a given moment, which moment to seek in the ephemerides? Until 1834, one used the real solar time of Paris in the *Connaissance des Temps*. Then, because of the existence of more reliable clocks, one used the mean time of Paris. In 1916, following an International Convention, one used the mean time of Greenwich. These time scales were all related to the rotation of the Earth known as uniform at that time. When irregularities were put into evidence in this rotation, astronomers introduced a new uniform time scale for use in the ephemerides, based on the rotation of the Earth around the Sun. Ephemeris Time compiled from Newcomb's theory of the Sun, or, as it was in the *Connaissance des Temps*, Temps Uniforme compiled from Le Verrier's theory of the Sun, were used. From 1984, Terrestrial Time, a uniform time scale derived from atomic clocks which were much more stable than celestial motions (see TIME SCALES: ATOMIC), was introduced.

Reference systems

Knowledge of the positions and the motions of celestial bodies requires a precise notion of the reference systems of space and temporal coordinates where one will locate the positions described by the ephemerides. We saw previously that the time argument of the ephemerides could not be taken in any time scale. In the same way, we will see that the spatial coordinates to be used must be attached to a reference system through a reference frame. One can distinguish the celestial and the terrestrial reference systems.

The celestial reference systems are either dynamical (based on the dynamical study of the motions of solar system's bodies) or kinematical (based on the statistical study of the motions of far bodies such as stars, galaxies and quasars). The dynamical reference celestial systems, first built in Newtonian mechanics, are built today in relativistic mechanics which ties the time argument to the spatial variables (see REFERENCE FRAMES AND TIME SCALES IN GENERAL RELATIVITY). For the needs of the current ephemerides, the definitions given previously for the time argument are sufficient. To link the positions of the celestial bodies to an observer located on the Earth, one will need also to define a terrestrial reference system.

The terrestrial reference system requires the knowledge of a model of Earth, its form and its deformations depending on time. The determination of a topocentric position requires such a system to know the position of the observer relative to positions of celestial bodies that are commonly determined in a geocentric celestial reference system.

The celestial reference frames

A reference system is a theoretical concept and the construction of ephemerides requires the knowledge of a reference frame which is the concrete materialization of a reference system. A celestial reference frame will thus be associated with dynamical theories, constants and star catalogs.

A reference frame is defined by a plane of reference and a given direction. For the ephemerides currently published, the plane of reference is the equator of the Earth (equatorial reference frame) or the ecliptic plane of the orbit of the Earth around the Sun (ecliptic reference frame). The direction of reference is that of the equinox, ascending node of the ecliptic on the equator, intersection of the two planes. These planes and this direction are related to the Earth and we will define various reference frames depending on the theories and the constants used to build them. Then, for each reference frame thus built, we will fix the planes and the direction of reference to obtain a perfectly defined reference frame.

Reference frames related to stars

These reference frames are defined by the positions and the PROPER MOTIONS of stars. The star catalogs provide a value of the proper motions which makes it possible to obtain, by a simple calculation, the position of stars at a given date. However, the Astronomisches Rechen Institut of Heidelberg, Germany, has published each year since 1960, following an international agreement, the apparent positions of the 1535 stars of the FK4 and FK5 catalogs in the *Apparent Places of Fundamental Stars*. New reference frames using stars of the HIPPARCOS catalogue and the very

far radiosources are under development to produce on international system of reference.

Dynamical reference frames related to the solar system's bodies
The dynamical models of the bodies of the solar system adjusted on radar or laser observations are independent of the stars of the catalogs and define a plane and a direction of reference. Associated with a theory of PRECESSION–NUTATION, they define a reference frame. Let us quote the reference frame related to numerical integrations DE405/LE405 of the Jet Propulsion Laboratory and the one related to the analytical theories ELP2000/VSOP82 of the Moon and the planets of the Bureau des Longitudes.

Coordinates systems

Once given a reference frame, it is necessary to choose the coordinates to be used in order to provide the positions in the ephemerides. For any reference frame, a theory for the precession–nutation is associated and one defines:

- positions in the mean reference frame (the fundamental plane is a mean plane, i.e. affected only by precession). An epoch must be given to fix the reference frame; this epoch is conventional (for example 1950 for reference frame FK4 and 2000 for the FK5).
- positions in the true reference frame (the fundamental plane is affected by precession and nutation). The epoch of the reference frame is that to which one gives the positions: the reference frame is not fixed, but this reference frame is the only one directly accessible to the observer.

In the reference frames thus defined, the coordinates may be:

- geometrical—they are the positions really occupied by the body at the date given, without taking into account the speed of the light;
- apparent—they are positions as seen by an observer being at the center of the reference frame. They are referred to a true reference frame of the date. The speed of the light and the annual aberration are taken into account.
- astrometrical or astrographic—these coordinates are directly comparable with the star catalogs. They may be deduced from the apparent coordinates by the transformation of precession–nutation to come back to a fixed reference frame (the one of the date of the star catalogs) and by the suppression of the annual aberration. The light time is still taken into account.

The ephemerides of position
Depending on the positions to be represented in the ephemerides, we have to choose a fundamental plane and some coordinates. For the ephemerides for the terrestrial observer, the fundamental plane will be the terrestrial equator and the coordinates to be provided will be the right ascension (angle counted towards the east starting from the equinox, along the terrestrial equator) and the declination (angle counted towards the north above the equatorial plane). The radius vector, the distance from the center of the reference frame to the considered body, may also be provided. This distance does not depend on the reference frame, except by taking into account the light time.

The ephemerides of the Moon, the Sun and main planets give apparent coordinates mainly for the guidance of telescopes. For Pluto, the asteroids and the comets, they provide the astrometrical coordinates directly comparable with the star catalogs. In the case of natural satellites, differential coordinates relative to the planet in a tangential plane with the celestial sphere, directly comparable with the photographic exposures or images from CCD cameras, are provided.

Let us quote the topocentric coordinates, centered on an observer situated on the Earth: these coordinates should be calculated for each observer, so, in order to transform the apparent coordinates into the topocentric ones, a small correction has to be added.

Positions may also be given in non-spherical coordinates such as rectangular coordinates: the x-axis being directed towards the equinox of the reference frame and the z-axis towards the celestial North Pole of this reference frame. Such ephemerides are mainly provided for space navigation.

Ephemerides concerning stars
The proper motions of stars are not sufficiently important to justify the publication of an ephemeris daily. Only the ephemeris of the polar star is provided daily in several ALMANACS, since this allows the setting up of telescopes.

Ephemerides for physical observations
In order to observe from the Earth the surfaces of solar system's bodies, it is necessary to define the parameters which will characterize the rotation of the body around its axis, to give some numerical values and to define a coordinate system in which the points on the surfaces may be located (planetographic or planetocentric reference frames). One then calculates the points of the body which are visible from the Earth at a given date. It is also useful to know quantities related to the illumination of the apparent disc. The definitions given hereafter were ratified by the International Astronomical Union.

Definition of the parameters of the rotation
The North Pole is, by definition, that of the two poles of the axis of rotation which is in the north side of the invariant plane of the solar system (near to the ecliptic). The parameters of the rotation of the solar system's bodies are, for each body:

- the axis of rotation which is given by the right ascension and the declination in the system J2000 of the direction of its North Pole, depending on time;
- the position of the meridian line origin which is given by the angle which separates the ascending node of the

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

equator of the planet on its orbit from this meridian line origin, angle counted in the equator of the planet and depending on time. A constant at the origin of time will be added if the meridian line origin is linked to a perceptible detail characteristic on the surface of the body.

Definition of the coordinates system
Two different coordinates systems are necessary to locate a point on the surface of a body:

- the planetocentric coordinate system where the planetocentric latitude of a point is the angle made by the vector, joining the center of the body and the point, with the equatorial plane; and where the planetocentric longitude is the dihedral angle between the meridian of the point and the meridian origin, counted positively towards the east on the body, independently of the rotation. This system is used for the study of the motion of a satellite over the body.
- the planetographic coordinate system used to chart the surface of the body. The planetographic latitude of a point of the surface is the angle made by the normal to the surface at this point with the equatorial plane. If the body is assimilated with an ellipsoid of equatorial radius a and of polar radius b ($b < a$), the planetocentric and planetographic latitudes φ and φ' of a point of the ellipsoid are connected by

$$\tan \varphi' = \tan \varphi / (1 - f)^2$$

where f is the flatness of the ellipsoid defined by $f = (a - b)/a$.

The planetographic longitude is defined in a way similar to the planetocentric longitude. It is also counted starting from the meridian line origin but in the direction opposed to rotation. It results from this that, for a distant observer, the planetographic longitude of the center of the apparent disc always increases with time, whatever the direction of rotation of the body. In order to respect a historical tradition and to be able to continue to use old charts, this rule admits exceptions for example for the Earth, the Sun and the Moon whose rotations are direct.

Accuracy of the ephemerides

The accuracy of the ephemerides is the result of three cumulative precisions chosen for the compilation of the ephemerides.

- The internal precision of the dynamical theories used to model the motions depends on the importance of the terms of the series neglected and may be evaluated by comparison to a numerical integration. Note that the numerical integrations have their own internal accuracy depending on the algorithms and the computers used. The internal precision is generally the best.
- The external precision of the theory depends on the accuracy of the observations used for the adjustment of the constants of integration (the external precision is the one limiting the total precision of the ephemerides).
- The precision of the representation is chosen when adjusting the number of coefficients and the length of the intervals of validity (this precision is chosen in order to avoid degrading the resulting accuracy).

Representation of the ephemerides

Ephemerides in tabular form
The oldest form of the ephemerides is the publication in the form of tables of positions, the interval of which depends on the variation of the values of the positions. The faster this variation, the smaller the interval should be between two values. A simple reading of the table and a visual interpolation are sufficient to find the observed object in the sky. However, in order to get a higher precision, a nonlinear interpolation is necessary. This will need more complex calculations using the published data. For a higher precision, a solution is to decrease the length of the time interval between two values and therefore to increase the volume of data to be published. The *Astronomical Ephemerides* and the *Annuaire du Bureau des Longitudes*, nowadays, and the *Connaissance des Temps* until 1979, contain tabulated ephemerides. Let us quote the motion of the Moon: in order to ensure an internal precision of a few units of 0.01 arcsecond, the ephemeris is tabulated with a 3 h interval. For each coordinate, this representation with a step of 3 h requires 2920 values annually (table 3). Instead, with the tabulated ephemerides, 7440 values were necessary to reach the same accuracy, but with more computer calculations (table 2). Let us quote also the case of the Galilean satellites of Jupiter which have an extremely fast motion around Jupiter. A tabulated ephemeris would have required a step every 20 min which would have led to a volume of data too large to be published in a printed ephemeris. The solution was of two kinds. The first way was to provide formulae, complex and long, to be implemented which would provide a precision of one tenth of a second of degree. The second way was to offer the reader a graphical chart, the reading of which led to a precision of one second of degree. This last method is quite weak but is sufficient to identify the bodies at the time of an observation.

The common widespread use of pocket calculators and microcomputers implies that the simplicity of the formulation is no longer fundamental in the compiling of the ephemerides. It is more important to preserve a good precision of representation over the period of time covered by the ephemeris. Thus, instead of evaluating a function $f(t)$ as a table of computed values at short intervals of time, it is better to establish valid functions of approximation of $f(t)$ on large intervals of time, with the concern to minimize the errors and the total volume of the data.

Approximation of a function
The goal of the ephemerides is thus to represent a function $f(t)$, derived either by the result of a numerical integration

or by an analytical function of the time, which describes the motion of a body or the temporal evolution of a phenomenon.

In the majority of the cases, the Chebyshev series are now used for the realization of the ephemerides. Why? In fact, any function can be approximated on a given interval of time by a polynomial, the degree and the number of terms of which increase as the interval of time increases. Such an approximation is not optimized and the volume of data to be published is significant. On the other hand its use is very simple since it is enough to substitute time in the polynomials thus built. Other representations are much better: let us try to explain why.

Chebyshev approximation

The functions to be approximated are always defined for all the values of the interval. The principle of the Lagrangian approximation is to adjust a polynomial of degree n on $n + 1$ tabulated values. It would obviously be more desirable to take into account all the values of the function. For this reason, the Chebyshev approximation is chosen: the polynomials of Chebyshev have the interesting characteristic of having the error regularly distributed on the considered interval and being stable during evaluation. Moreover, among the various types of polynomial approximations, the approximation of Chebyshev is the one with the lower degree and the one on which the error does not exceed a given value. Another interesting fact is that the last retained terms offer an estimate of accuracy of the polynomial representation.

The approximation function of the ephemerides will thus represent the true function by developments in Chebyshev polynomials defined on successive intervals of times. This method of representation makes it possible to compress the volume of data and to calculate the positions of the bodies quickly. For these reasons, it is very well adapted to the needs of astronomers (amateurs, professionals, theoreticians, astrometrists, etc).

The Chebyshev ephemerides appear as a succession of coefficients $a_0, a_1, \ldots a_n$ for a coordinate given on an interval $[t_1, t_2]$. The use of these ephemerides is as follows. The calculation of the value of the coordinate at the time t of the interval $[t_1, t_2]$ is done by carrying out the change of variable: $x = -1 + \{2(t - t_1)\}/\{t_2 - t_1\}$. Therefore x belongs to the interval $[-1, +1]$. The Chebyshev polynomials of the first kind $T_n(x)$ are given by the relation: $T_n(x) = \cos(n \arccos x)$. One can also calculate them using the relation of recurrence: $T_n(x). = 2x.T_{n-1}(x) - T_{n-2}(x)$ with $T_0(x) = 1$ and $T_1(x) = x$. The position is then calculated through the following sum: $a_0.T_0(x) + a_1.T_1(x) + \cdots + a_n.T_n(x)$ will provide the result.

Approximation by mixed functions

As we have seen, the polynomial approximation is not the only one. The introduction of mixed functions, makes it possible to take into account the quasi-periodical character of the functions appearing in the ephemerides. Indeed, a function of a quasi-periodical nature may be approximated on a given interval by a development in polynomials of relatively low degree n, but the fact that the function is quasi-periodical on the interval, which is the case in the motion of the bodies of the solar system, is not taken into account.

Let us see, through an example, how to benefit from the quasi-periodical nature of a function. Let the even function be $f(x) = \cos x + \cos 2x$. It is much better represented with the base of functions $1, \cos x, \cos 2x, \cos 3x \ldots$ than with the polynomials $1, x^2, x^4, x^6, \ldots$ or with any other basis of even polynomials.

However, an ephemeris is not so simple but it is possible, on a given interval of time, to make the approximation using several periodic functions, the period of which is suggested by the physical nature of the problem (for example the period of revolution of a celestial body), and also using some secular terms (or some polynomials of time) because of the not rigorously periodic nature of the described motion.

The representation using mixed functions is particularly well adapted to the motions of natural satellites of planets, and more generally for the motions of short period bodies, the motion of which is never far from a periodical motion. In the *Connaissance des Temps*, the differential coordinates of the natural planetary satellites are described by coefficients of mixed functions on intervals covering several revolutions of the satellites and are easy to calculate using the following formula:

$$f(t) = a_0 + a_1 t + b_0 \sin(\nu t + \varphi_0) + b_1 t \sin(\nu t + \varphi_1) + b_2 t^2 \sin(\nu t + \varphi_2) + c_0 \sin(2\nu t + \psi_0)$$

where $2\pi/\nu$ is a period close to the period of revolution of the body; a_j, b_j, and c_j, are the amplitudes; φ_j and ψ_j are the phases ($j = 0, 1, 2$). This formula rises from the choice of the selected basis. The mixed terms have the form: $at^k \sin(p\nu t + \psi)$ (k and p: integers; a: amplitude; ψ: phase). The maximum values of k and p are adjusted according to the required precision. If the interval of representation is widened, it will be necessary to enrich the basis by mixed terms in power of time and multiple of the basic frequency. However, if the interval decreases, it is necessary to modify the basis in order to avoid the loss of precision (this is not the case with a polynomial representation, the precision of which increases when the interval decreases).

The status of current research on ephemerides

The first way to improve ephemerides (i.e. to improve the accuracy of the positions provided by the ephemerides) is to improve the theories used for the motions of the celestial bodies. At the present time, an effort has been made to take into account all the gravitational effects occurring in the solar system and to include the relativistic effects. Improved observations are needed and, for the inner planets (Mercury to Mars), the radar observational method has led to the abandonment of optical observations. For the giant planets, optical observations are still the only way to observe the positions of the planets together with

the small number of positions sent by the space probes. The observation of planetary satellites is now preferable to the use of direct observations of the planets themselves. At last, the determination of the DYNAMICAL REFERENCE FRAME (a reference frame deduced from the motion of the Earth around the Sun) and the linkage to the independent stellar reference frame (no longer based on stars but on very far sources; see also EXTRAGALACTIC REFERENCE FRAMES) is the last step for the improvement of the ephemerides, solved by spatial observations from artificial satellites such as Hipparcos in the past and Fame or Gaia in the future.

The second way to improve ephemerides is to use better representations of the motions. In fact, the problem is mainly in the reduction of the amount of data. Chebyshev approximation is still in use for that purpose.

Various supports used for the publication of the ephemerides

Printed ephemerides

Although microcomputers are omnipresent for astronomical calculations, the printed ephemerides are still abundantly fused by professional and amateur astronomers. Why? First of all, the observer often needs a confirmation or a simple approximate position. Opening a book and directly reading a position is easy. One can also find:

- hours of rising and setting of the Sun and the Moon (and also of principal planets);
- positions of the bodies of the solar system and bright stars for a terrestrial observer;
- ephemerides for the physical observations of these bodies.

These ephemerides are in general of weak precision and a tabulated form is sufficient.

Let us quote also some specialized ephemerides such as the *Nautical Almanac* or the *Ephémérides Nautiques* published for navigational use. However, not all the printed ephemerides provide tabulated positions. Graphical representations may be provided (essentially for the Galilean satellites of Jupiter) as well as coefficients for polynomials (in the case of high precision ephemerides) needing the use of a pocket calculator or a microcomputer. This is the case for the *Connaissance des Temps* since 1979 which before then was used for the manual programming of telescopes or more simply for the tests and the checks of more complex software.

The following is a list of the main printed ephemerides published nowadays:

- by the Institut de Mécanique Céleste/Bureau des Longitudes, France: *Connaissance des Temps*, *Annuaire du Bureau Des longitudes*, *Ephémérides Nautiques*;
- by H M Nautical Almanac Office of the former Royal Greenwich Observatory now at the Rutherford Appleton Laboratory, United Kingdom and by the Nautical Almanac Office of the USNO, USA: *Astronomical Almanac*, *Nautical Almanac*:
- by the Institute of Applied Astronomy, St Petersburg, Russia: *Ephemerides of Minor Planets*;
- by the Astronomisches Rechen Institut, Heidelberg, Germany: *Apparent Places of Fundamental Stars*.

Electronic ephemerides

The paper medium is traditional for the ephemerides which have existed for centuries. Nowadays, the use of the printed ephemerides is limited to specific help. The search for a body in the sky or the guidance of a telescope following a fast object of the solar system is now made in an automatic way by using electronic ephemerides.

The first way is to have the printed ephemerides put on a medium (diskettes, CD-ROM) associated with a program of reading and of calculation of a position at a given date. It is obvious that the calculations of positions using the basic dynamical theories is not possible in real time because of the complexity of calculations and of the volume of data to be handled. The reading of tabulated values followed by their interpolation (not easy) or better, the reading of coefficients followed by precise calculations of the associated positions is today commonly used. For the calculations of positions not taking place in real time, it is also possible to carry out interactive calculations online using a specialized server. Web servers on the Internet allow these calculations now and ephemerides of high precision are thus available for all. The high precision ephemerides used by professional astronomers and by the space agencies are provided, of course, in an electronic form. The following is a list of addresses of the most interesting professional servers reachable on the Internet.

Server of the Jet Propulsion Laboratory, Pasadena, CA, USA: http://ssd.jpl.nasa.gov/

Server of Institut de Mécanique Céleste/Bureau des Longitudes, Paris, France: http://www.bdl.fr/

Epicurus of Samos (341–270 BC)

Greek philosopher, founded Epicurean philosophy in Athens, which divided the universe into 'atoms' and the 'void.' Epicureans regarded happiness as the chief human good, attainable through freedom from anxiety and fear, and their materialism was despised in subsequent years as anti-Christian.

Epoch

A particular instant of time used for reference purposes. In the context of the measurement of stellar positions, the epoch of observation is the date on which the observational data were obtained. A catalog for the epoch 2000.0, for example, would list positions, valid for that date. To obtain positions at some other epoch, the effects of proper motion must be calculated. Other effects such as nutation and aberration have also to be taken into account in order to obtain a precise position for an object on a particular date.

Note that the epoch of observations of star positions does not have to be the same as the equinox to which the coordinate system is referred. The positions of a high proper motion star at epochs 1972.3, 1984.5, 1999.1 could be plotted in the coordinate frame of the equinox 1950.0, for example.

In the context of planetary motion, the term 'epoch' may be used to describe the time of perihelion passage (the time at which the planet makes its closest approach to the Sun), this being one of the elements of the orbit.

Epsilon Aurigae

This star, sometimes known as 'Almaaz' or 'Al Anz', is an eclipsing binary of the same type as Algol, but of exceptionally long period. It is a pale yellow supergiant of spectral type F0Ia, apparent magnitude 3.03v. It is intrinsically brilliant (absolute magnitude −6.0), its luminosity having been estimated as about 200 000 times that of the Sun, but it is 2040 light-years away, with a parallax of 0.002″. The eclipses last for about a year, and occur at intervals of 27.1 years; the next eclipse is due in 2010.

Epsilon Lyrae

Though not very bright, this is a favorite test object for powerful binoculars and small telescopes. Situated 1.6° north-east of Vega, it is known as 'the Double Double'. The star can just be seen to be double with the unaided eye, under good conditions by observers with acute eyesight. With binoculars it is easily separated, the component stars being 3.5′ apart at a position angle of 173°. It is in fact a quadruple star system, each component being itself a binary. With a good 3 inch (7.5 cm) refractor both can be resolved. The system is 160 light-years distant (parallax 0.020″).

The first component system, ε^1 Lyr, which has a combined apparent magnitude of about 4.7, consists of two white stars separated by 2.5″ at position angle 353°, with an orbital period of about 1165 years. The apparent magnitude of ε^1 Lyr A is 5.06, its spectral type A3V and absolute magnitude 1.6; ε^1 Lyr B has an apparent magnitude of 6.19, spectral type F1V and absolute magnitude 2.7.

The second system, ε^2 Lyr, has a combined magnitude of about 4.6 and is very similar to the first pair. It again comprises two white stars, separated by 2.3° at position angle 87°, orbital period 585 years. The apparent magnitude of ε^2 Lyrae C is 5.30, its spectral type A5V and absolute magnitude 1.8; ε^2 Lyr D has an apparent magnitude of 5.51, spectral type F0Vn and absolute magnitude 2.0.

Equation of Time

An equation giving the difference between apparent solar time (or sundial time) and mean time. Thus:

$$\text{equation of time } (E) = \text{apparent solar time (AT)} - \text{mean time (MT)}.$$

A positive value E means that apparent time is ahead of mean time. A negative value of E means that apparent time is lagging behind mean time.

The difference arises for two reasons. First, since the Earth moves round the Sun in an elliptical orbit, when the Earth is near perihelion it moves faster than when it is near aphelion; consequently, the apparent motion of the Sun relative to the background stars is more rapid near perihelion than near aphelion. This variation in the Sun's apparent motion affects the length of the apparent solar day. Second, although the real Sun's apparent motion is along the ecliptic, the variation in the length of the apparent solar day depends upon the daily change in the right ascension of the Sun. This change in RA is equal to the projection of the Sun's ecliptic motion onto the celestial equator, and is maximum near solstices and minimum near equinoxes.

As a result of the combination of these two effects, mean time and apparent solar time can differ by up to 16.3 min. Apparent time is ahead of mean time between about 16 April and about 15 June and, again, between about 2 September and about 26 December, the difference reaching maxima of about 3.75 and 16.3 min on 15 May and 4 November, respectively. Apparent time lags behind mean time during the rest of the year, the difference reaching maxima of 14.3 min and 6.3 min on 12 February and 27 July, respectively.

Equatorial Mounting

A telescope mounting in which one axis of rotation (the polar axis) is aligned parallel to the Earth's axis, and the other (the declination axis) is aligned at right angles to this axis, in the plane of the celestial equator. Rotation about the polar axis allows the telescope to be pointed towards celestial bodies with different right ascensions or hour angles, while rotation about the declination axis enables the telescope to be swivelled perpendicular to the celestial equator in the direction of increasing or decreasing declination. The advantage of the equatorial mounting is that the apparent diurnal motion of a celestial body can be followed by driving the telescope in the opposite direction to the Earth's rotation (i.e. driving from east to west) at a rate of one revolution per sidereal day around the polar axis only. The disadvantages of the equatorial mounting are that it is more complex and expensive to construct than the altazimuth mounting, and gravitational loadings change in a complex way as the telescope moves, so making it difficult to compensate for structural flexure. Nevertheless, until comparatively recently, the overwhelming majority of large telescopes were set up on equatorial mountings.

There are many varieties of equatorial mounting. Popular varieties include the German, cross-axis and fork mountings. In the German mounting, the declination axis sits across the top end of a short polar axis, with the telescope at one end and a counterbalancing weight at the other. In the cross-axis mount, a long polar axis is supported at top and bottom by two pillars, or piers, and the telescope is attached to a declination axis that crosses the polar axis roughly mid-way between its top and bottom ends. Once again, the weight of the telescope is counterbalanced by a weight placed at the opposite end of the declination axis. In the fork mounting, the telescope swings in declination about two pivots attached at opposite sides of the upper end of an open U-shaped fork, the bottom of which is attached to a short polar axis.

Equator-S

Small German satellite launched in December 1998 to investigate Earth's equatorial magnetosphere. Operations began in February 1999, but ceased after three months due to a system malfunction. The first satellite to receive positional information from GPS satellites while beyond geostationary orbit.

Equinox

An instant at which the Sun crosses the celestial equator; the Sun is then vertically overhead at the equator, and day and night have equal duration at every point on the Earth's surface. The apparent annual path of the Sun on the celestial sphere is inclined to the celestial equator and intersects it at two points. The terms vernal equinox and autumnal equinox are applied to these points.

Star positions are measured in celestial coordinates based on a particular vernal equinox, say the equinox of the year 2000. Thus, the word 'equinox' applied in the context of the position of a star defines the coordinate system being used.

Equuleus

(the Little Horse; abbrev. Equ, gen. Equulei; area 72 sq. deg.) A northern constellation which lies between Delphinus and Pegasus, and culminates at midnight in early August. Its origin is uncertain, though its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

Equuleus is the second smallest of the 88 constellations (and the smallest in the northern sky) with only one star, α Equulei (Kitalpha), magnitude 3.9, brighter than fourth magnitude. Interesting objects include ε (or 1) Equulei, a quadruple star system consisting of two pale yellow (F5 and F7) components, magnitudes 6.1 and 6.4, separation 0.9″, period 101 years, the former of which has an unseen companion which revolves around it in a period of 2.03 days, and a fourth, yellow (G0) component, magnitude 7.4, separation 10.3″.

There are no bright star clusters, nebulae or galaxies in Equuleus.

Eratosthenes of Cyrene (*c*. 276–*c*. 196 BC)

Astronomer, philosopher, geographer and geometrist (developed theorems in prime number theory), born in Cyrene (now Shahhat, Libya) became librarian in Alexandria. Eratosthenes made a surprisingly accurate measurement of the size of the Earth. Having heard that at the summer solstice the Sun illuminated the bottom of a well at Syene (now Aswan, south of Alexandria), and was therefore overhead, he observed the angle of the Sun off the zenith on the same day at Alexandria. He measured the distance between the two cities, allegedly by counting the rotations of the wheel of a carriage driven between them, and determined the circumference of the Earth as 250 000 stadia (47 000 km, compared to the true value of 40 000 km). He also measured the tilt of the Earth's axis with great accuracy obtaining the value of 23 degrees 51 minutes.

Eridanus

(the River; abbrev. Eri, gen. Eridani; area 1138 sq. deg.) A southern constellation which lies between Cetus and Orion and extends from the celestial equator to within 32° of the south celestial pole. The center of the constellation culminates at midnight in mid-November, though its brightest star is on the meridian a month earlier. Eridanus has been associated with several different terrestrial rivers, notably the Nile, which also lies south–north, and the Po, into which, in Greek mythology, Phaëthon, son of the Sun-god Helios, was said to have fallen after Zeus struck him with a thunderbolt during his abortive ride of his father's chariot. The brightest stars of Eridanus south to about dec. −40° were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*; the more southern ones (including its brightest star) were added in Renaissance times and are shown, for example, in Bayer's *Uranometria* of 1603.

A large but rather inconspicuous constellation, the brightest stars in Eridanus are α Eridani (Achernar), which at magnitude 0.5 is the ninth brightest star in the sky, β Eridani (Cursa), magnitude 2.8, and γ Eridani (Zaurak), magnitude 3.0. There are 14 other stars of magnitude 4.0 or brighter. Interesting stars include ε Eridani, which at magnitude 3.7 is one of the nearest naked-eye stars (distance 10.5 light-years) and a similar star to the Sun, θ Eridani, a fine binary with bluish-white (A4 and A1) components, magnitudes 3.3 and 4.4, separation 8.3″, o^2 Eridani (Keid), a triple-star system with an orange (K1) primary, magnitude 4.4, a white dwarf secondary, magnitude 9.5, separation 93″, and a third, red dwarf (M4.5) component, magnitude 11.2, which orbits the latter, separation 9.0″, period about 248 years, and has a mass of only about 0.2 that of the Sun, and 32 Eridani, another binary with yellow and bluish-white (G8 and A2) components, magnitudes 4.8 and 6.1, separation 6.5″. Other interesting objects include NGC 1535, a tenth-magnitude planetary nebula, and NGC 1291, a ninth-magnitude spiral galaxy.

Eros

The first Amor asteroid to be discovered, independently by Gustav Witt and Auguste Charlois in 1898, designated (433) Eros. The asteroid orbits the Sun at a mean distance of 1.46 AU, or 218 million km (perihelion 1.13 AU, aphelion 1.78 AU), in a period of 1.76 years; inclination 11°–, eccentricity 0.22. Its rotation period is 5.3 h. Eros is an S-type asteroid, with a reflection spectrum similar to that of ordinary chondrite and stony-iron meteorites. It was the prime target of the NEAR Shoemaker probe, which entered orbit around Eros on 14 February 2000. Images returned showed an irregular, elongated object measuring 33 × 13 km, with a 7 km diameter crater. The slight deviation to the probe's trajectory revealed that Eros has a bulk density of about 2.5 g cm^{-3}. At 3:02:10 EST on 12 February 2001, the NEAR Shoemaker spacecraft landed on the surface of Eros, the first spacecraft ever to land on an asteroid. It traveled its last mile by cruising down to the surface of Eros at a gentle 4 mph (1.9 m s^{-1}), finally coming to rest after its 2 million mile journey. The last image snapped by the spacecraft was a mere 394 ft (120 m) from the asteroid's surface and covered an area 20 ft (6 m) square.

Escape Velocity

The minimum velocity required in order that an object can leave the surface of, or depart from any other point within the gravitational field of, a massive body and recede to a large distance. In principle, if atmospheric resistance is ignored, a projectile fired vertically from the surface of a massive body at its escape velocity will continue to move away with a speed which decreases with increasing distance but does not decline to zero until it has receded to an infinite distance. An object moving through the gravitational field of a massive body will, in general, follow a parabolic trajectory; for this reason, escape velocity is sometimes called parabolic velocity. The escape velocity at the surface of the Earth is about 11.2 km s^{-1} (6.96 miles). The velocity of escape from the less massive Moon is about 2.4 km s^{-1} at its surface. A planet cannot long retain an atmosphere if the planet's escape velocity is low enough to be near the average velocity of the gas molecules making up that atmosphere.

Eta Aquarids

A meteor shower that takes place in late April and May. The radiant lies in the constellation Aquarius. The Eta Aquarids occur when the Earth intersects the descending node of the meteor stream from Halley's Comet; the Orionids in October are produced by the Earth's passage through the ascending node. Because Halley's orbit is retrograde, Eta Aquarid meteoroids impact the Earth at a high relative velocity and produce fast meteors. There are records of this shower dating back to 74 BC.

Eta Carinae

One of the most enigmatic stars known. It is an S Doradus-type eruptive variable, situated at the heart of the bright diffuse nebula NGC 3373. It is obscured by the Homunculus Nebula, a bright cloud of gas and dust ejected by the star itself during a major outburst in 1843, when it reached an apparent magnitude of -0.8, becoming temporarily brighter than all other stars except Sirius. Its apparent magnitude is at present 6.2 but varies erratically over decades and it has been recorded as faint as 7.9. It is an extremely powerful source of infrared radiation, and is believed to be a highly luminous blue star much of whose visible radiation is absorbed by the nebula and re-emitted in the infrared. Because of the obscuration its spectral type, parallax and absolute magnitude cannot be determined with any certainty.

It has been variously suggested that η Carinae is a very young star in its pre-main-sequence stage, or an extremely old star in the closing stages of its evolution, which is now believed more likely. The last phase of its existence could well result in one of the most spectacular supernova explosions ever witnessed, but there is no means of reliably predicting when this will occur.

Eta Carinae Nebula

A bright, diffuse nebula, NGC 3373, surrounding the star η Carinae. About 2° across and divided by a dark, V-shaped, obscuring dust-lane, it contains a number of interesting stars and star clusters, and also two major included nebulae—the bright Homunculus Nebula and the dark, absorbing Keyhole Nebula. Its distance has been estimated as about 8000 light-years.

Ether (or Aether)

A transparent, weightless medium which was imagined by nineteenth-century physicists to fill all space, and to provide the medium through which electromagnetic waves could propagate. Conventional physical ideas of the time did not admit of waves that could travel through 'nothingness'. The concept of the ether came to be associated with the idea of absolute space, the ether providing a background to the universe against which all motion could be measured.

Experiments were devised, notably the Michelson–Morley experiment, to try to measure the motion of the Earth through the ether, and these all failed to detect any such motion, however small. The null result of these experiments was explained by the theory of relativity, first published in 1905. The ether, being undetectable, became an unnecessary hypothesis, and has been abandoned (along with the Newtonian concept of absolute space).

See also: Michelson–Morley experiment.

Eudoxus of Cnidus (*c*. 400–*c*. 347 BC)

Greek astronomer, mathematician, born in Cnidus (on the Resadiye peninsula, now Turkey). First astronomer to produce a detailed description of the stars and constellations. His work is now lost but known through the extensive borrowing by ARATUS in his *Phenomena*. Proposed a geocentric system for the solar system in which the Sun, Moon and planets moved on spheres centered on the Earth. The model failed to account for variations in the observed diameter of the Moon or changes in the brightness of planets, which were correctly interpreted to indicate that their distances were changing. He noticed some of the discrepancies with observations and tried to adjust the model by postulating that each sphere had its poles set at an angle to the next sphere. His model contained no mechanical explanation and was only a mathematical description, but the spheres came later to be regarded as having a physical reality. Some of his mathematics became a foundation for parts of Euclid's *Elements*, indeed may have been due to him.

Euro-Asian Astronomical Society

The Euro-Asian Astronomical Society (EAAS) was created in April 1990, and is active mainly in New Independent States (NIS), the former USSR territory. Its members include professional NIS astronomers, astronomical associations and institutions worldwide.

Its purpose is to maintain and develop NIS astronomy and to reinforce scientific contacts between astronomers of NIS and the rest of the world.

The society organizes astronomical meetings, astronomical education and related topics. It supports library programs and provides free of charge, or very cheap, subscriptions to Russian-language astronomical/space research journals and magazines for astronomical institutions of NIS and some Central European countries (except Russia).

Its publications include a professional English Journal, Astronomical and Astrophysical Transactions, a popular Russian publication translated into English, *Universe and Ourselves*, and an electronic newsletter, in Russian but translated into English.

Europa

Europa is the smallest of the four large 'Galilean' satellites of JUPITER. Table 1 gives its basic parameters. Little known before 1979, when the VOYAGER spacecraft returned the first close-up images, it has recently been a prime target of the Jupiter-orbiting GALILEO MISSION, which has provided major advances in our understanding of Europa. Its icy surface and rocky interior, and strange surface topography of low-relief ridges and chaotic terrain, make Europa one of the most unusual objects in the solar system. Most intriguing is the possibility that this unusual surface overlies a liquid ocean, which might conceivably support life.

Table 1. Properties of Europa.

Radius	1561 km
Density	3005 kg m^{-3}
Mean distance from Jupiter	671 000 km
Orbital eccentricity	0.0101
Surface composition	H_2O ice, hydrated minerals (perhaps salts or H_2SO_4); SO_2; O_2; CO_2; H_2O_2
Interior composition	Silicate rock; Fe/FeS; H_2O

Origin

Europa was presumably formed at the same time as its three siblings, IO, GANYMEDE, and CALISTO, from the same cloud of material, the proto-Jovian nebula, that formed Jupiter itself. Temperatures in the proto-Jovian nebula would have been highest near Jupiter, with ice condensing only in the outer parts. Europa formed near the inner margin of the ice zone, and so acquired a little ice in addition to rock and iron. The solid material in the nebula accumulated into ever-larger pieces which were drawn together by mutual gravitational attraction, until four large bodies, the nascent Galilean satellites, became large enough to sweep up the remaining debris. After formation, the satellites were driven away from Jupiter by their tidal interaction with the planet. Eventually the inner three became locked by mutual gravitational perturbations into the present orbital resonance, in which Io orbits Jupiter twice for every orbit of Europa, and Europa orbits twice for every orbit of Ganymede, a circumstance that has profound consequences.

Interior

Europa's mean density, 3000 kg m^{-3}, is much greater than the density of water, 1000 kg m^{-3}, but is significantly less than the density of around 3500 kg m^{-3} that would be expected if the interior were made entirely of silicate rocks. Its interior is strongly differentiated, with a probable iron or iron sulfide core, a thick mantle of silicate rock, and an outer layer of water or ice. The DIFFERENTIATION of Europa indicates that at some time its interior has been hot and mobile enough for the heavier constituents to settle towards the center. Heating during its formation, radioactive decay, or tidal heating may have been responsible. Unlike its neighbor Ganymede, Europa does not generate a significant internal magnetic field, though as the origin of Ganymede's field is a mystery we are not yet sure what this means for Europa. However, Europa perturbs Jupiter's magnetic field in a way that implies an electrically conducting layer, such as a liquid ocean, not far below Europa's surface. The same appears to be true on Callisto, a geologically dead moon that otherwise looks very different from Europa. The orbital resonance with Io and Ganymede makes Europa's orbit significantly non-circular, so although Europa rotates synchronously, keeping the same face to Jupiter, the tidal bulge raised by Jupiter changes size and orientation slightly during the orbit as Europa's distance from Jupiter varies. This continual distortion dissipates energy inside Europa, in a milder version of the tidal heating that produces Io's volcanos. Dissipation is greatest in the parts of the interior that deform the most during the orbit, but the amount of deformation of the ice or rock depends on its viscosity,

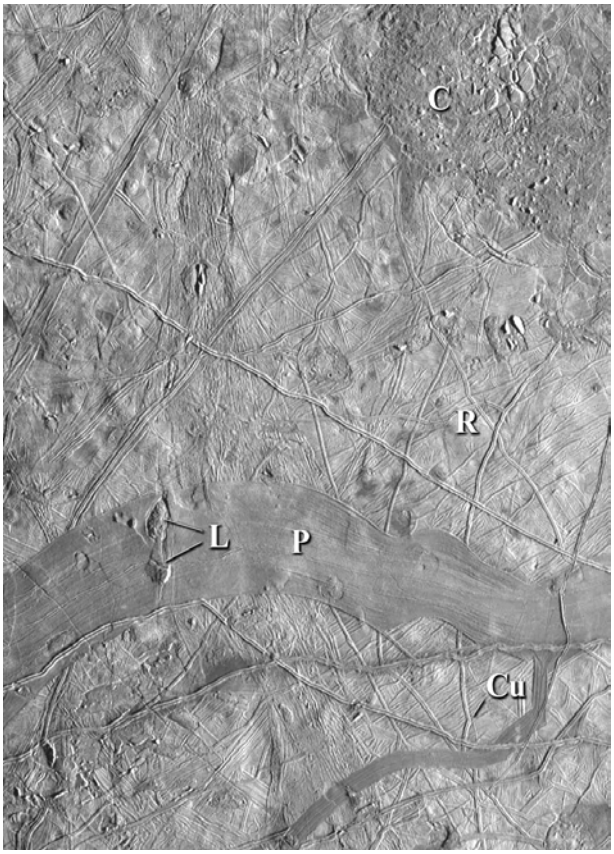

Figure 1. Galileo image of a 215–280 km region of Europa's surface, showing the wide variety of surface features. Examples are shown of ridged plains (R); chaos (C); lenticulae (L); a pull-apart band (P); and one 'cusp' of a cuspate ridge (Cu). Note the almost complete absence of impact craters.

Dirac House, Temple Back, Bristol, BS21 6BE, UK

which depends on its temperature, which in turn depends on the amount of tidal heating, so there are complex feedback mechanisms that are difficult to model. However, it seems likely that most of the dissipation occurs in the lower, warmer, part of the solid ice layer, and that the heating rate is roughly 0.05 W m^{-2} or less.

Surface geology

Europa's surface can be divided into several very distinct types of terrain (figure 1), each of which is described separately below.

Ridges

Much of Europa's surface is made up of innumerable overlapping ridges, tens to hundreds of meters high and up to thousands of km long. The more recent ridges tend to stand higher than the older ones, and are often flanked by diffuse regions of lower ALBEDO. Most frequently, the ridges are double, with a central trough, but some have multiple components. Some are remarkably straight, while others have irregular, lobed, margins, and others have strikingly regular 'cuspate' forms, like the path of a bouncing ball seen from the side. These are most likely formed from propagating fractures that spread in a direction that changes periodically during each orbit of Europa because of changing stresses from Jupiter's tides. The most extensive ridges are global in extent, and with their dark margins form the dark 'fractures' that are Europa's most distinctive feature in global views. The double ridges seem to start life as simple fractures, which then somehow gradually develop ridges on either side. If the fracture opens further, additional ridges may appear within the central trough, producing complex sets of ridges. The ridges may develop by upwarp of the material on either side of the fractures by shallow intrusions along the fractures, or by accumulation of debris on either side of the fracture. The debris may accumulate either by 'volcanic' eruption along the fracture, or squeezing of material out of the fracture by its periodic opening and closing, perhaps by daily tides.

The ridges form a global pattern that provides evidence that Europa's outer shell is detached from its interior, and due to Jupiter's tides rotates very slightly faster than the interior, completing a full rotation relative to Jupiter over thousands or millions of years. The shell will be distorted and stressed as it rotates over the tidal bulge that always faces Jupiter, and the expected stresses from this process very nicely explain the global alignment of the ridges, and the apparent changes in their orientation with time. Rhythmic changes in the stress direction during each orbit of Jupiter may even explain the remarkable 'cuspate' ridges, if each 'bounce' of the ridge forms during a single Europan day.

Pull-apart features

In many areas, the ridges are broken by smoother, darker, bands where the surface has clearly been pulled apart: features on either side of the band match up perfectly, as in figure 1. The smooth material in the band is new material that has filled the gap as the surface on either side separated, much like sea-floor spreading on Earth. The global distribution and orientation of the pull-apart features suggests that they open in response to stress from the daily tides. Somewhere on Europa, there must have been compression of the surface to make room for the observed spreading, and it is odd that no unambiguous compressional features have yet been identified.

Chaos and lenticulae

Large areas of Europa's surface have been fractured and broken up to form 'chaos'. Large chaos regions may be more than 100 km across, while the smaller but similar lenticulae are typically 10 km in diameter. A possible evolutionary sequence for lenticulae can be inferred. In places the original surface is simply domed up; elsewhere the dome is fractured, frequently to the point where the original surface texture is unrecognizable. Chaos regions are similar but larger. The fractured blocks of original surface have often been moved horizontally, rotated, or even tilted: much of the nearby original surface must have been destroyed to make room for this motion. Chaos and lenticulae are generally darker than the original surface: the dark mottled terrain seen in global views is mostly chaos. Both types of terrain appear to have formed by disruption of the surface from below, probably due to enhanced local heating. However, whether the heating involved large-scale melting, with the broken crustal fragments floating like icebergs, or simply the rising of warm, mobile, solid ice towards the surface, is not yet clear. Feedback between ice viscosity and tidal heating, discussed above, may produce local thermal runaway and explain the patchy distribution of the chaos regions.

Impact features

Europa's surface is more lightly cratered than most PLANETARY SURFACES, an indication of its relative youth. The largest craters seen so far, Tyre and Callanish, roughly 80 km in diameter, are composed of many concentric circular fractures surrounding a rough central region. The concentric fractures suggest that the impacts penetrated the rigid outer layer of Europa into a fluid layer below: the fractures would have formed as material rapidly flowed towards the center of the hole created by the impact. The Galileo spacecraft has shown craters larger than 25 km in diameter are extremely flat compared to similar sized craters on other bodies, and are also surrounded by multiple concentric rings. It is likely that these craters have penetrated the ice into the probable

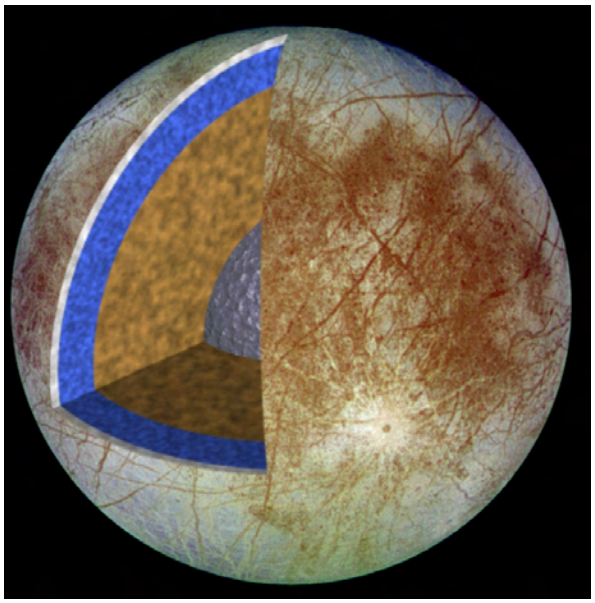

Figure 2. Full-disk view of Europa from Galileo. The bright impact crater Pwyll is conspicuous. A cutaway shows a schematic of the interior structure: the cold, rigid outer icy crust (white), the possible liquid water ocean or warm ice layer (blue), the silicate layer (brown), and the central iron core (silver). This figure is reproduced as Color Plate 28.

ocean below. Smaller impacts, such as the bright ray crater Pwyll (figure 2), 25 km in diameter, look superficially like lunar craters, with a sharp rim and central peak, and thus probably did not penetrate to a fluid layer. Taken together, these constraints imply a thickness of 10–20 km, though the models are incomplete, and uncertainties remain for the rigid outer layer, They also do not prove that the underlying fluid layer is liquid water: very warm, mobile, ice is also possible. Pwyll-sized craters are extremely flat compared to lunar craters, showing that even the 'rigid' outer layer is soft enough below the surface to flow and fill in the original hole.

Age of the surface

The age of the geological features on Europa's surface is difficult to determine precisely. No detectable changes occurred in the 17 years between the Voyager and Galileo images: if we assume that changes occur smoothly and uniformly over Europa's surface, this implies an average surface age of at least 30 million years. The surface age can also be estimated from the abundance of impact CRATERS, combined with estimates of the rate at which impacts are expected to occur. Cratering rates can be determined, though not very accurately, from the number of observed comets and asteroids near Jupiter. Our best estimates suggest that Europa's surface age is somewhere between 10 and 300 million years. If this age estimate is correct, it is very likely that geological activity on Europa continues today: the chance that activity would have persisted for 95–99% of Europa's history and then stopped just before humans appeared on the scene is small. This raises another mystery, however. Chaotic terrain on Europa is more recent than ridged plains in almost all areas of Europa so far surveyed. If Europa's surface is young, why would geological activity have changed so dramatically so recently? One possibility is that activity on Europa is cyclic, driven by complex interactions between its interior and its orbit, and that at some future date the style of activity will change back from chaotic terrain formation to ridged plains formation.

Interaction with Jupiter's magnetosphere

Europa is immersed in Jupiter's enormous magnetosphere, which rotates with Jupiter once every ten hours (see JUPITER: MAGNETOSPHERE), much faster than Europa's 3.5-day orbital period. The magnetosphere carries with it a dense plasma of energetic ions, dominated by sulfur and oxygen ions that have escaped from Io. Lacking a strong intrinsic magnetic field that could deflect the plasma, Europa's surface, particularly the trailing hemisphere (the side that faces backwards as Europa orbits Jupiter), is thus continually bombarded by energetic ions. The bombardment has two main effects: implantation and erosion.

The strongest direct evidence for implantation is an absorption feature in Europa's ultraviolet spectrum, due either to sulfur dioxide or sulfur–oxygen bonds in some other form. The feature is strongest on the trailing hemisphere, where bombardment is strongest. There is also a pervasive darkening of Europa's trailing hemisphere at longer ultraviolet wavelengths. It is likely that some of the bombarding sulfur ions become embedded in the water ice of Europa's surface, and combine with oxygen from the surrounding water to produce the UV absorption feature. It is also possible that the UV feature is due to sulfur intrinsic to Europa, concentrated on the trailing side by sputtering away of water ice, as explained in the next paragraph.

Each ion that collides with Europa's water ice also ejects many water molecules, or fragments of water molecules, from the surface—a process known as sputtering. Most of the material re-impacts Europa elsewhere on its surface, but a significant fraction is moving fast enough that it escapes into space. It is estimated that, on average, 5–20 cm of ice is lost from Europa every million years, and 20–80 cm is transported large distances across the surface. The fact that geological features on Europa as small as tens of meters in size have not been worn down to nothing by this process provides additional evidence that the surface is relatively young, less than 100 million years old. Sputtering of the surface ice also supports a tenuous oxygen atmosphere around Europa, which was detected by the Hubble Space Telescope. There is also a faint but detectable halo of sodium

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

around Europa, perhaps also derived ultimately from Io.

Recent images from the Hubble Space Telescope show a faint far–ultraviolet auroral 'footprint' on Jupiter's upper atmosphere at the point where a Jovian magnetic field line connnects Europa to Jupiter. This shows that Europa is electrically conducting, probably through its tenuous ionosphere, and drives electrical currents between itself and Jupiter as it moves through the Jovian magnetic field. Io and Ganymede show similar, but stronger, auroral footprints.

Ocean? Life?

The most intriguing question about Europa is whether there is an OCEAN of liquid water beneath the ice that might even support life. Many observations, including the pull-apart features, evidence for nonsynchronous rotation of the outer shell, the fractured and rotated blocks in the chaos regions, and the unusual appearance of Europa's impact craters, point to the existence of a soft, mobile layer a few kilometers beneath a rigid outer crust. The big question is then whether this layer is warm ice not far below its melting point, or is actually liquid. The evidence for nonsynchronous rotation, and electromagnetic evidence for a liquid layer beneath the surface, are perhaps the strongest evidence for an ocean rather than warm ice. Hybrid models, in which a 'lithosphere' of cold, rigid ice overlies warmer, convecting ice, which in turn overlies a liquid ocean, are also plausible.

If an ocean has existed over most of Europa's history, conditions there may be suitable for the development and sustenance of life. Organic (carbon-based) molecules that provide the raw material for life are common in the solar system, and while sunlight probably does not penetrate the outer ice shell, tidal heat may have supplied sufficient energy for the chemical reactions necessary for life. A commonly drawn analogy is with the living communities that exist independently of sunlight, sustained only by chemical and thermal energy from the EARTH'S INTERIOR, around the hydrothermal vents or 'black smokers' on the floors of the Earth's oceans. Currently, however, we have no direct evidence for life on Europa, and further exploration will be required to determine whether oceans or life really exist there (see also LIFE ON OTHER WORLDS).

Future exploration

Plans are being made for a Europa Orbiter mission that could be launched as early as 2003 and might enter Europa orbit around 2008, with the primary goal of establishing the existence (or otherwise) of a subsurface ocean. In addition to the usual cameras and spectrographs, the spacecraft would probably carry a radar to probe beneath the surface, with the possibility of detecting any ocean directly. A laser altimeter and gravity measurements would directly detect the distortion of Europa's surface as its distance from Jupiter changes—a thin ice shell over an ocean would distort more than a thick layer of solid ice. After the orbiter mission, landers that could sample the surface directly, and eventually probes that could drill through the ice to the ocean (if it exists) are being considered. The technical challenges of these missions, particularly the large quantity of fuel required to rendezvous with Europa, and the harsh radiation environment, are extreme, and overcoming them will be challenging. Europa will keep many of its secrets for a while longer.

Europa Orbiter

Proposed mission to investigate Jupiter's moon Europa. Part of NASA's Outer Planets/Solar Probe Project. Possible launch in November 2003. May carry a radar sounder to measure the thickness of the surface ice and detect any underlying liquid ocean. Other instruments would reveal details of the satellite's surface and interior processes.

European Astronomical Society

The European Astronomical Society was founded in 1990 to 'contribute to and promote the advancement of astronomy, in its broadest sense, in Europe by all suitable means'. It counts over 1500 members and has 18 affiliated societies. It publishes a newsletter and organizes every year a Joint European and National Astronomical Meeting (JENAM).

For further information see http://www.iap.fr/eas/.

European Southern Observatory (ESO)

ESO is an intergovernmental European organization with its headquarters, scientific and technical divisions in Garching near Munich. It was founded in 1962 to establish and operate an astronomical observatory in the southern hemisphere and to promote and organize cooperation in European astronomical research. Its member states are Belgium, Denmark, France, Germany, Italy, The Netherlands, Sweden and Switzerland.

The original observatory at La Silla is located in one of the most arid areas in the world, the Chilean Atacama Desert, 600 km north of Santiago. Since the land was acquired in 1964, 14 optical telescopes have been built on La Silla mountain, 2400 m above sea level.

The most recent addition (in 1989) was the 3.5 m New Technology Telescope (NTT), one of the world's most advanced optical telescopes. The NTT operates with the SUSI camera and the multimode EMMI (visual) and SOFI (infrared) instruments.

The largest instrument at La Silla is a 3.6 m telescope equipped with the ADONIS adaptive optics unit and a high-resolution spectrograph. An infrared instrument and a high-accuracy radial velocity spectrograph are also planned.

Other facilities include the MPG/ESO 2.2 m wide-field instrument, the 1.52 m telescope with its new FEROS spectrograph, and the Danish 1.54 m telescope. The newly installed Swiss 1.2 m Leonard Euler telescope with the CORALIE echelle spectrograph is successfully 'hunting' for planets around other stars.

The 15 m Swedish–ESO submillimeter telescope (SEST) became operational in 1987. A new bolometric array will pave the way for the ATACAMA LARGE MILLIMETER ARRAY (ALMA).

ESO is also completing the Very Large Telescope (VLT) on the 2635 m high Mount Paranal, 130 km south of Antofagasta in Chile. The VLT will comprise four 8.2 m reflecting unit telescopes and several moving 1.8 m auxiliary telescopes. Their light beams will eventually be combined in the VLT interferometer (VLTI). When completed, the VLT will be the largest optical telescope in the world. On October 29, 2001, ANTU and MELIPAL, two of the four VLT 8.2 m Unit Telescopes were successfully linked. Light from the southern star Achernar (Alpha Eridani) was captured by the two telescopes and sent to a common focus in the observatory's Interferometric Laboratory. Following careful adjustments of the optical paths, interferometric fringes were soon recorded, proving that the beams from the two telescopes had been successfully combined in phase. From an analysis of the observed pattern (the fringe contrast), the angular diameter of Achernar was determined to be 1.9 milli-arcsec. At the star's distance (145 l.y.), this corresponds to a size of 13 million km. The observation is equivalent to measuring the size of a 4 m long car on the surface of the Moon.

European Space Agency (ESA)

An international organization whose task is 'to provide for and to promote, for exclusively peaceful purposes, cooperation among European states in space research and technology and their space applications'.

ESA has 14 member states: Austria, Belgium, Denmark, Finland, France, Germany, Italy, Ireland, The Netherlands, Norway, Spain, Sweden, Switzerland and the United Kingdom. Portugal became the fifteenth member in 2000. Canada takes part in some projects under a cooperation agreement.

The agency was born in 1975 from the merging of two existing organizations: ESRO (the European Space Research Organization) which developed satellites, and ELDO (the European Launcher Development Organization) which was responsible for development of a European launch vehicle.

ESA's activities cover space science, Earth observation, telecommunications, space segment technologies including orbital stations and platforms, ground infrastructures and space transportation systems, as well as basic research in microgravity.

ESA's headquarters are in Paris. Other ESA establishments include: the European Space Research and Technology Centre (ESTEC) in The Netherlands; the European Space Operations Centre (ESOC) in Germany; the European Space Research Institute (ESRIN) in Italy; the European Astronaut Centre (EAC) in Germany and a launch center at Kourou in French Guiana.

The science program, in which all member states participate, is one of the agency's mandatory activities. The program originated in the days of ESRO, which launched seven scientific satellites. ESA has played a leading role in an additional 13 scientific missions (including the Hubble Space Telescope) since the agency began operating on 31 May 1975.

The ESA science program is based on a long-term plan, known as Horizons 2000, which was adopted in 1985. The most expensive and ambitious missions, which are called Cornerstones, include the Solar and Heliospheric Observatory (SOHO) and Cluster II (combined as the Solar–Terrestrial Science Program), the X-ray Multi-Mirror (XMM) mission, the Rosetta comet mission and the Far Infrared Space Telescope (FIRST).

Four missions are under study for the next three Cornerstones: the BepiColombo Mercury orbiter, the LISA gravitational wave observatory, the GAIA astrometric interferometer and the IRSI Infrared Space Interferometer mission.

ESA has also launched a number of small and medium class missions, including Hipparcos, Ulysses, the Infrared Space Observatory (ISO) and the Huygens probe to Titan. In addition, the International Gamma-ray Laboratory (INTEGRAL) is scheduled for launch in 2001.

Medium missions have now been replaced by smaller, cheaper missions which offer faster development times and more frequent launch opportunities. These are divided into Flexible missions, which are purely scientific, and SMART (Small Missions for Advanced Research in Technology) missions, in which demonstration of new technologies takes precedence over science. The first example of a Flexible mission will be Mars Express, scheduled for launch in 2003. The main purpose of the SMART-1 mission to the Moon, due to launch in 2002, will be to demonstrate ion propulsion.

Also under study are MiniSTEP, a 2003 mission in collaboration with NASA, to test the equivalence principle, and an ESA contribution to the Next Generation Space Telescope.

Evening Star

A name given to Venus when it is visible in the west after sunset. Ancient astronomers believed that morning and evening apparitions of Venus were of two different planets; the evening planet was given the name Hesperus. As the evening star, Venus is moving from superior conjunction (when it lies behind the Sun) to inferior conjunction (when it is between the Earth and the Sun), and is visible for longest when it reaches the position known as greatest elongation east, when its angular separation from the Sun is greatest. The name 'evening star' is sometimes given to evening apparitions of Mercury.

Excitation and Ionization

Excitation: general properties

The excitation of a region reflects the physical conditions taking place in the astrophysical environment. The state of excitation is generally determined from the observation of spectral lines arising from different excited levels of an atom, ion or molecule. The analysis of the emitted spectrum allows the determination of the column densities[1] of the emitting levels, provided that the RADIATIVE TRANSFER of the emitted spectrum has been taken into account and that the fundamental atomic or molecular physics data are known. In some cases, absorption studies also allow the derivation of excitation conditions. This is currently performed in visible and UV absorption studies of a variety of atomic and molecular species towards diffuse and translucent clouds lying in front of a bright background star.

An *excitation temperature* can be defined from the ratio of the column densities of two excited states expressed by Boltzmann's law where the kinetic temperature is replaced by the excitation temperature $T_{\rm exc}$:

$$N(J)/N(J-1) = (g_J/g_{J-1})\exp(-\Delta E_{J\to J-1}/kT_{\rm exc})$$

where $N(J)$ is the column density of a level labelled by the J quantum number, g_J is the corresponding statistical weight, $\Delta E_{J\to J-1}$ the difference of the level energies and k is Boltzmann's constant. The ratio of the column densities is assessed to be the same as the ratio of the abundances. The physical significance of the temperature may be questioned but the value is useful as a clue to the excitation process.

The comprehensive time variation of the atomic, ionic or molecular level populations is expressed as the balance of excitation and deexcitation processes and can be put to zero at steady state if the timescales involved are shorter than the evolution time of the astrophysical region. The general set of equations is expressed as:

$$n_u\left(\sum_{k\neq u}(n\gamma_{u\to k}+R_{u\to k})+\sum_{k<u}A_{u\to k}\right) = \left(\sum_{u\neq k}n_k(n\gamma_{k\to u}+R_{k\to u})+\sum_{k>u}A_{k\to u}n_k\right).$$

$\gamma_{u\to k}$ stands for the collision rate coefficient in $\mathrm{cm^3\ s^{-1}}$, which induces the u to k transition due to a perturber of density n. For sake of simplicity, only one type of perturber has been written in the expression but several partners may be involved. In a hot ionized gas, electrons and protons are the most efficient perturbers, in atomic interstellar clouds, atomic hydrogen and helium are the exciting agents whereas in comets water molecules are the most abundant species. The excitation and deexcitation collision rate coefficients satisfy the so-called microscopic detailed balance equations:

$$g_u\gamma_{u\to k}\exp(-E_u/kT) = g_k\gamma_{k\to u}\exp(-E_k/kT).$$

The collision deexcitation rate coefficients depend generally smoothly on the temperature, and are often expressed as a power law of the temperature. $A_{u\to k}$ represents the spontaneous emission probabilities in $\mathrm{s^{-1}}$. The emitted lines can be of different kinds. Permitted lines are electric dipole transitions. Astrophysical environments are often favorable to forbidden line emission[2], because they are far from equilibrium. A famous example is the green nebular oxygen lines connecting the ground ^{3}P level to ^{1}D level which is an electric quadrupole transition or the green coronal Fe^{13+} line connecting the two fine structure levels of the ground ^{2}P state which is a magnetic dipole transition. $R_{k\to u}$ represents photon stimulated processes. Radiative excitation is described by $R_{k\to u}$, the absorption probability. Stimulated emission may also occur under specific conditions, for example when a population inversion is completed: maser emission is indeed observed in dense clouds associated with some embedded energy sources and is usually characterized both by variability and high polarization. Stimulated processes are proportional to the incident radiation field intensity, which depends on the astrophysical environment, and to the Einstein $B_{k\to u}$ coefficient, which is a pure atomic or molecular property.

If the radiation field involved in the radiative induced processes depends on the line itself, then on the level populations, the equations become nonlinear and the system has to be solved iteratively. This is the case in the envelopes of SUPERNOVAE as in SN 1987A or in molecular emission of abundant species such as CO in dense interstellar clouds.

At thermal equilibrium, the collisions dominate and the excitation temperature is equal to the real (kinetic) temperature. A convenient concept is the critical density which is the lower limit above which thermodynamical equilibrium is satisfied. It is defined as the ratio between the radiative deexcitation probability and the collisional deexcitation rate coefficient connecting two levels. The populations of the different levels are only dependent on the equilibrium between collisional excitation and deexcitation. However, the astrophysical environments are most often far from thermal equilibrium and the excitation follows then from detailed microscopic processes.

[1] The column density is defined by the integration of the density of the species along the line of sight. If the medium is homogeneous, it is simply given by the product of the density by the length of emitting region. Its unit is $\mathrm{cm^{-2}}$.

[2] A forbidden transition is characterized by a low emission probability since it arises from at least second-order perturbation terms in the matter–radiation interaction. In other words, forbidden lines result from *non*-electric dipole transitions, i.e. magnetic dipole or electric quadrupole.

Sources of excitation

Collisional excitation

In GASEOUS NEBULAE, many common ions have low-lying energy levels with excitation potentials of order kT_e, where T_e is the electron temperature. Then the electrons in the extended tail of the Maxwell distribution corresponding to about 10 000 K have sufficient energy (≈2–4 eV) to excite the first spectral terms of O^+, O^{2+}, N^+, S^+. Once these levels are excited, they radiate spontaneously back to the ground state via forbidden transitions. The emissivities of the corresponding lines are simply $j_\lambda = N_u A_{u\to\ell} hc/\lambda$, where A is the Einstein coefficient of the transition taking place at the wavelength λ. Studying intensity ratios of lines corresponding either to close or to very different excitation energies, one will probe the density or temperature conditions. It is important to recognize that these transitions not only are diagnostics of physical conditions, but represent also the path through which the kinetic energy of the incident particles is converted into photon energy, depicting in that way a cooling process. In the cooler interstellar mostly atomic environments, the fine structure line of C^+, whose transition energy expressed in K is 92 K, is a major coolant of these regions at about 100 K. With a wavelength of 158 μm, in the far-infrared, this transition has been extensively studied by the Infrared Space Observatory (ISO) satellite launched in November 1996 by the European Space Agency (see INFRARED SPACE MISSIONS). Also detected by ISO are the electric quadrupole lines of molecular hydrogen observed in dense warm shocked regions at about 500–1000 K. In dense cold molecular clouds, rotational transitions of CO and its isotopes as well as other molecular species become valuable probes of the medium and the main coolants.

Radiative excitation

It has been recognized earlier that other excitation mechanisms are involved. This is the case of the fluorescence, so-called Bowen, lines in the visible observed in the spectra of high excitation PLANETARY NEBULAE since 1935. The important factor is the fluorescence efficiency defined as the ratio between the photon rate of fluorescent emission and the creation rate of pumping photons. In the equilibrium state, the rate of creation of pumping photons is equal to the total destruction rate including all loss processes. The incident pumping radiation is provided by the available He^+ Ly α photons whose wavelength at 30.3780 nm is almost coincident with a resonance line of O^{2+} at 30.3799 nm. The emission of vibrationally excited molecular hydrogen in REFLECTION NEBULAE is another manifestation of radiative excitation. The photons produced by nearby bright stars excite electronic transitions of molecular hydrogen which subsequently fluoresces and cascades inside the ground electronic state via vibrational infrared transitions. Finally, let us mention the excitation conditions derived from absorption studies of the CN molecule in diffuse and translucent clouds. It turns out that the rotational temperature of about 2.8 K reflects the excitation by the cosmic background radiation field with which the molecule is in quasi-equilibrium. This interpretation required more that twenty years.

Ionization: general properties

The IONIZATION of a medium is determined by the abundance of electrons. The number density of ions is then obtained by the requirement that the total charge is zero. The concomitant presence of electrons and ions could suggest that permanent electric fields be present. However, due to the inverse square law force applying between electric charges, the distance over which an appreciable electrostatic field can be created by a charged particle embedded in a plasma is determined by the Debye length L:

$$\frac{1}{L^2} = \frac{e^2}{\varepsilon_0 kT} \sum n_{i0} Z_i^2$$

usually very small compared to the cosmic scales involved. For fully ionized hydrogen $L = 69(T/n)^{1/2}$ in SI units. Electrostatic forces may however come in to play when large magnetic fields are also present over large distances.

The ionization of a medium is of crucial importance for its large-scale properties. For selected ranges of the ionization rate, several phases may coexist in pressure equilibrium. Each stable phase is determined by the onset of a new cooling mechanism or the decline of a heating mechanism, all of which are highly dependent on the relevant microscopic atomic and molecular processes.

Ionized species present in astrophysical regions involve a large variety of atomic positive ions, some with a very large nuclear charge due to extreme conditions of density and temperature. Molecular ions are also present in cold regions such as interstellar clouds and cometary environments. Negative ions are rarely considered due to their low stability against surrounding photons or collisions. The role of H^- is however undeniable and its presence in the atmospheres of cool stars is conspicuous from the continuum opacity arising in the photodetachment process. Large molecules such as polycyclic aromatic hydrocarbons (PAH) or hydrogenated amorphous carbons (HAC) which are invoked to explain the unidentified infrared emission lines at 3.3, 6.2 and 12 μm, may be somewhat negatively charged due to their large attachment probabilities. Interstellar dust particles may also be partially ionized; their charge is positive in the outer edges of interstellar clouds and may be negative in the central parts of molecular clouds.

In thermodynamic equilibrium, the ionic abundances are dependent on the temperature and the electronic density via the Saha equation. If we consider an atomic species A in two arbitrary states of ionization r and $r + 1$, then the number densities of the corresponding populations are related by the following expression: $n_{r+1} n_e / n_r = f_{r+1} f_e / f_r$. f_r, f_{r+1} and f_e are the partition functions of the ions of charge r and $r + 1$ and of the electrons, respectively. If one keeps only the ground-state contribution, labelled by a superscript 0, in the partition

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

functions of the ions, the Saha equation has the more familiar expression:

$$\frac{n(A^{r+1})n_e}{n(A^r)} = 2\frac{g^0_{r+1}}{g^0_r}\left(\frac{2\pi m_e kT}{h^2}\right)^{3/2} \exp(-\Phi_r/kT).$$

g^0_r, g^0_{r+1} are the statistical weights of the ions in their ground level, and Φ_r is the ionization energy of the A^{r+} ion. This approximation is often used to calculate the sources of opacity of bound–bound and bound–free transitions of the available elements in the stellar interiors for their various stages of ionization.

Sources of ionization

Photoionization

In gaseous nebulae, ions result from the balance between photoionization of atoms followed by radiative recombination. Photoionization is induced by energetic photons emitted by central bright stars surrounded by mostly hydrogenic gas. The ejected electrons then recombine with the protons to give back atomic hydrogen. However, excited electronic levels are efficiently populated in the recombination process, which cascade subsequently by emitting radiative transitions in the radio, millimeter, visible and ultraviolet wavelength range. The beautiful blue or red colored shapes displayed in nebular observations are indeed coming from the Balmer α and Balmer β lines arising from recombination. Other minor elements are present in these regions showing up in emission spectra over the full range of the electromagnetic spectrum. In the radio range, emission occurs between Rydberg levels with large values of the principal quantum number ($n \approx 100$). The analysis of the recombination spectrum allows the determination of the electronic density and the temperature which is a few thousand K, much below the temperature corresponding to thermal ionization. In addition to discrete spectral lines, the interaction of the electrons with the ions gives rise to a weak continuous radiation which, in the radio and infrared regime, is dominated by free–free transitions due to bremsstrahlung. The corresponding photons delineate the distribution of the nebular gas and allow the derivation of the density of electrons via the so-called emission measure[3].

Photoionization is also the ionization agent in SUPERNOVAE REMNANTS where a compact galactic x-ray source illuminates the gas. Photoionization can then involve inner shell electrons and is often followed by the emission of one or more Auger electrons. These ionization processes are heating mechanisms of the gas whereas the subsequent emission of the gas is a cooling process. Other processes may contribute to the heating as, for example, direct Compton scattering on the electrons. The ionization and temperature of the gas may reach a stationary state depending on the gas pressure and the flux and spectrum of radiation.

[3] The emission measure is the integration along the line of sight of the square of the electron density. Its unit is usually cm^{-6} pc.

The ionization equilibrium can be modified by additional processes when they compete efficiently with one of the basic mechanisms mentioned above. Charge transfer with atomic hydrogen may drive the equilibrium towards ionization stages which photoionization models, including radiative and dielectronic recombination processes, cannot account for. This occurs in planetary nebulae for several low and intermediate excitation lines in C^{2+}, N^+, O^+, etc. This recognition has been the origin of a large number of theoretical studies on charge transfer collisions involving multiply charged ions.

Collisional ionization

In the absence of ionizing radiation, the local ionization state is mainly controlled by collisions of ions with thermal electrons as, for example, in the solar CORONA. Electron impact ionization is also taking place in the hot interstellar gas component which has been found thanks to O^{5+} absorption. The dominant processes are electron impact excitation and ionization followed by radiative recombination, dielectronic recombination and bremsstrahlung. Dielectronic recombination occurs at specific resonant energies corresponding to weakly bound autoionizing states leading to a much larger rate coefficient so that dielectronic recombination dominates radiative recombination in high temperature plasmas by factors of about a hundred. If ionization comes only from thermal electrons, the master equations describing the variation with time of the fraction f_r of element X in each ionization stage involve the electron density in front of each term. So, at steady state where $\mathrm{d}/\mathrm{d}t = 0$, the electron density is removed so that the ionization balance of the ion fractions is only dependent on temperature. We should point out that this situation cannot be described by a state of thermodynamic equilibrium since it does not result from detailed balance of time-reverse processes (e.g. photoionization versus radiative recombination, electron impact versus three-body recombination). In dense molecular clouds, the ionization results from the interaction of the gas with COSMIC RAYS, which are energetic particles such as protons and alpha particles probably produced during the explosion of supernovae. The ionization fraction of the medium is presumably small and cannot be determined directly since all ions present are not observable. Then, the ionization is deduced from millimeter observations of molecular ions (HCO^+) and interpreted from chemical models. The OH radical is another tracer of cosmic rays in cold interstellar clouds since the first step of its chemistry involves the presence of protons or H_3^+ ions. The inferred cosmic ionization rate is of the order of 10^{-17} s^{-1}.

Exit Pupil

The image of the objective formed by the eyepiece of a telescope. All of the rays collected by the objective pass through the exit pupil, which is where the pencil of rays emerging from the eyepiece has its smallest diameter and the illumination of the image is greatest. The exit pupil, therefore, is the best place at which to place the pupil of the eye when observing with a telescope.

The diameter of the exit pupil (D_e) is equal to the aperture of the telescope (D) divided by the magnification (M). For example, a telescope with an aperture of 200 mm and a magnifying power of 50 will produce an exit pupil with diameter $D_e = D/M = 200/50 = 4$ mm. The diameter of the exit pupil must be less than or equal to the diameter of the pupil of the eye if all the light collected by the telescope is to enter the observer's eye. To meet this condition, the magnification must be greater than or equal to D/D_p, where D_p is the diameter of the pupil of the eye. Since the diameter of the dark-adapted pupil is about 7 mm, the minimum magnification that will ensure that exit pupil is smaller than the observer's pupil is approximately $D/7$, where D is the aperture expressed in mm ($D/0.007$ if D is in meters).

Exobiology

Exobiology (=bioastronomy, astrobiology) is the study of life in the universe. More precisely, it is the study of the origins, evolution and distribution of life in the universe and of the structures and processes associated with life itself (see also LIFE: ORIGINS AND POSSIBLE DISTRIBUTION IN THE UNIVERSE).

Historical background

From myths to the emergence of a new scientific field

Is there life elsewhere? This is certainly one of the oldest question asked by humankind. Mentions of it have been found, for instance, in Epicurus' 'Letter to Herodotus', 300 BC. Since antiquity, all over the world, many authors have thought about, discussed and written their feelings about this fundamental problem. In the 13th century, the Chinese philosopher Teng Mu wrote 'how unreasonable it would be to assume that apart from the Earth and the sky that we see, there are no other skies, nor other Earths'. Some have perished because of this idea. GIORDANO BRUNO (1548–1600) was burned by the Roman Catholic Church, because, as he wrote in his 'Del' infinito universo e mondi', he thought that 'There are countless suns and countless earths orbiting around their sun, exactly as our seven [sic] planets orbit around our Sun. Living beings inhabit those worlds.' GALILEO GALILEI (1564–1642) was promoting analogous ideas but, fortunately, he just escaped a similar destiny, by abjuring his 'mistakes and heresies' in front of the Court of the Supreme and Universal Inquisition. Later on, the question of life elsewhere was considered by many writers, philosophers and even scientists such as Kepler, Fontenelle, Kant, Goethe and Huygens. FLAMMARION, at the end of the 19th century was probably one of the first to ask 'What to do to bring evidence of these other worlds?'. The long story of the detection of so-called canals on the Martian surface brought a false answer to the question of life on Mars until the beginning of the 20th century. Then the development of more and more powerful tools for exploring other worlds, by remote sensing, and more recently by *in situ* techniques, opened a large avenue in this area and marked the true emergence of this new scientific domain of exobiology (see also LIFE ON OTHER WORLDS).

A new field is born

When NASA started the Apollo program, with the project of sending men to the Moon and bringing lunar samples to the Earth, the question of the possible presence of (indigenous) life on our natural satellite arose logically. The problem was in fact double : if there were life forms on the Moon, it was essential to avoid any biological contamination of our satellite by terrestrial organisms, and—even more important—of the Earth by hypothetical lunar organisms present in the lunar samples carried back to our planet. Thus, in the 1960s, planetologists and microbiologists alike started to work together to tackle this question. This was the time when the recipient of the Nobel Prize Award (1958) in Medicine and Physiology,

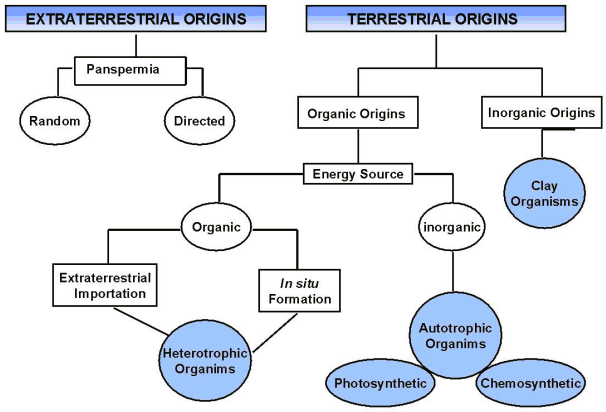

Figure 1. Diagram of theories of the origin of Life on Earth (from W L Davis and C P McKay).

Joshua Lederberg, invented the word 'Exobiology'. It then became a fully recognized scientific field, spanning many classical domains, including astrophysics, astronomy, planetology, physics, chemistry, biochemistry and biology, as well as human sciences and even mathematics.

The various approaches

Indeed, the approaches abound. The more logical and direct way is to search for life on extraterrestrial planetary objects. This can be done by remote sensing measurements or even, with the availability of space technologies, by *in situ* exploration. It can also be carried out by studies of extraterrestrial samples transferred to the Earth through natural processes (meteorites, micrometeorites, cosmic dust particles and cometary materials) or collected in space by robots or manned missions. Remote sensing techniques can even be applied to search for biological activity on extrasolar planets, when techniques become powerful enough to detect Earth-like objects and the presence of molecular oxygen and ozone in large amounts in their atmosphere (assuming that this is an unambiguous signature of life). The other approach is to assume that what happened on Earth is a common event in the universe and that there are numerous places in our Galaxy where life arose and evolved toward intelligent and technologically developed living systems. Then, by listening to the universe in the right direction and at the right frequency (presumably radiowaves) and at the right time, one should be able to detect signals from extraterrestrial civilizations. This is the SETI (search for extraterrestrial intelligence) approach mainly based on radio observations. There is a less direct approach but fully logical: the study of the terrestrial example, and, first of all, of the origin of life on Earth. By putting together the pieces of the puzzle of the origins of the first living system on our planet, one should be able to put some constraints in the conditions necessary for the emergence of life, in general, on a planetary body. Furthermore, the variety,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

distribution and limits of life on Earth would yield the—so far—unique example of distribution and evolution of life in the universe.

The terrestrial example

What is life ?

The only example we have—the terrestrial one—allows us to characterize life through a set of properties the simultaneous presence of which is specific to living systems. The most important are the properties of autoreproduction, of evolution and of mutation with a very high level of information included in the structures of the living systems, and with the property of autoregulation against the constraints induced by its environment. The terrestrial example shows that, starting from a simple unicellular living system, our last universal common ancestor (LUCA), a primitive prokaryotic cell, biological evolution has been able to induce a fantastic biological diversity. In spite of the many differences between the incredibly wide variety of species which live on Earth today, life on Earth shows a large unity. In fact these differences are seen mainly at the macroscopic level. As soon as we look at living systems with a microscope, we can observe that all are made of cells. From one in the unicellular, to billions in the pluricellular, the cell can be considered as the structural unit of life. Eukaryotes have cells with a clearly differentiated nucleus and prokaryotes are cells without a nucleus, but all cells have roughly the same structure and include the same kind of macromolecules, isolated from the outside by a membrane made of lipids. This selective frontier allows, through complex chemical mechanisms, the selection and concentration of all molecules necessary to the building of the cell, to its development and to its replication. The cell is the microscopic chemical plant for life , the place where all the life specific, chemical processes, are in progress, involving molecules also specific to life.

The building blocks

The unity of life is even clearer at molecular level. All living systems on Earth use the same type of molecules and, first of all, macromolecules: nucleic acids and proteins. In all (terrestrial) living systems cellular multiplication is programmed from the chromosomes, made of nucleic acids. These macromolecules include the genetic information which makes one living system different from another. The message is stored in deoxyribonucleic acid (DNA). It is transcribed and transferred to the ribosome (the cellular plant) where it is translated and converted, with the help of the genetic code, allowing the synthesis of proteins, the other macromolecules fundamental to life. Proteins play a crucial role in almost all biological processes. They can act as a very specific and powerful catalyst, with the protein enzymes, as a transport and storage molecule (e.g. hemoglobin transporting oxygen), or as a mechanical support, such as collagen, etc.

Nucleic acids are made of a very large number of units, called nucleotides, constituted of a five-carbon sugar, ribose in RNA or deoxyribose in DNA, linked to a phosphate molecule and to a one- or two-ring organic molecule called a nucleotide base (such as adenine). The smallest DNA molecule uses several thousand nucleotides and the largest one several billions. However, all use only four different nucleotides, only differing by their nucleotide base. Similarly, all RNAs on Earth are made of only four different nucleotides, using the same kinds of bases as DNA. From this alphabet of only four letters, nature can make a very large number of words, by using many letters and by changing their sequence from one to another nucleic acid.

The primary structure of proteins is based on the same principle, although their building blocks—called amino acids—are simpler than nucleotides. Among the very large number of different amino acids, proteins use only 20. This alphabet of 20 letters provides, again, a fantastically rich vocabulary, based on long words using a large variety of sequences. Furthermore, these molecules (with the exception of the simplest amino acid, glycine) possess an asymmetric carbon and consequently can exist under two different configurations, called enantiomers, and labelled 'L' and 'D', symmetric but not superimposable (this property is called 'chirality', and the molecules are said to be 'chiral'). Only one is used by life: the 'L' configuration for amino acids and the 'D' for sugars, and consequently for nucleotides.

To understand the origin of life it is essential to understand the origin of proteins and nucleic acids but also the origin of chirality in the living systems.

The origins of life

The study of the origins of life on Earth has probably been one of the most successful approaches in exobiology, even before the emergence of the field. Historically, the problem of the origin of life had for centuries almost only one answer: spontaneous generation. Although debated and discarded at least for macroscopic life, in the middle of the 19th century many still though that life could emerge spontaneously and suddenly from inert matter. With his—now historical—experiment on spontaneous generation Pasteur demonstrated in the 1860s that the observation of the spontaneous creation of microorganisms from non-living matter is only a false interpretation of observational data and can be explained by the biological contamination of the samples via the microorganisms present in the ambient air. Then, for more than 50 yr, the theory of the origin of life was mainly based on the concept of panspermia. It assumes that living germs are present everywhere in the universe and can travel in the cosmos, simply pushed by the pressure of radiation released by stars. They would have reached the solar system and seeded the Earth. The panspermia theory is not fully given up today; however, the generally accepted theory is based now on a thoroughly different concept of 'chemical evolution'. Already emerging from several writings of the 19th century, in particular in Darwin's letters, the concept of chemical evolution was first clearly

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

introduced and described by the Soviet biochemist Oparin, in 1924. The main idea is to assume that life arose on the Earth after a long evolution of organic (containing chemically reduced carbon, i.e. carbon in a non-oxidized form) but inert materials preceding Darwin's biological evolution and allowing, by natural chemical processes of a now so-called 'pre-biotic chemistry', the formation of structures of increasing complexity, up to the first replicating system. For Oparin, our ancestor would have been a 'heterotrophic' (living system unable to synthesize itself the organic molecules it needs) microorganism, fed by the many organic compounds present on the primitive Earth, produced in the atmosphere and in the primordial oceans by abiotic (without the involvement of life) processes. This vision has now markedly changed and it seems more likely that the first living system was an 'autotroph' (living system able to synthesize itself the organic molecules it needs), feeding from the inorganic molecules, in particular carbon dioxide, present in its environment. In addition several scenarios are invoked to explain the origin of the simple organics which are involved in this prebiotic chemistry. However, the general concept of a chemical evolution from simple to complex organic compounds, and to the first bio-macromolecules capable of replication, remains the same.

Table 1. Some key molecules of prebiotic chemistry.

Name	Formula	Prebiotic role
Hydrogen cyanide	HCN	Source of amino acids, of purine and pyrimidine bases
Cyanoacetylene	HC_3N	Source of pyrimidine bases
Cyanogen	NC-CN	Condensing agent
Liquid water	H_2O	Fundamental solvent
Formaldehyde	HCHO	Source of sugars
Hydrogene sulfide	H_2S	Source of S-containing compounds
Phosphate	PO_4^{3-}	Source of P-containing compounds

The first experimental evidence of this theory was provided in 1953 by the publication of the now well-known experiment by Stanley Miller. By simulating in a reactor the evolution of a model of the primordial atmosphere of the Earth under energy deposition, in the presence of liquid water, Miller was able to obtain amino acids. This also opened the new field of prebiotic chemistry. Since 1953, hundreds of similar experiments have been carried out, using various conditions (energy sources, composition of the gas mixture, etc). They show that the production of organic molecules, including amino acids and nucleotide bases, can be obtained, but only if the starting atmosphere is chemically reducing. They also show the importance of several simple organic molecules, such as formaldehyde, HCHO, hydrogen cyanide, HCN, cyanoacetylene, HC_3N and other nitriles, because of their chemistry in liquid water. Now, although we have no direct information on the conditions on the primitive Earth, the current models are in favor of an oxidizing atmosphere. This drastically reduces the importance of atmospheric processes in the formation of organics on the primitive Earth. However, other sources can be envisaged. The deep-sea hydrothermal vents, which include many chemical ingredients able to induce prebiotic syntheses, are now considered to have been a possible place on the primitive Earth where chemical evolution to life started. Another possibility is to assume that a large part of the starting carbonaceous ingredients necessary to prebiotic chemistry was imported from space. Indeed, the Earth is continuously bombarded by extraterrestrial materials (meteorites, micrometeorites, interplanetary dusts and cometary matter) a noticeable fraction of which includes organics. It is likely that these bombardments were even more important on the primitive Earth and thus may have been a source of organics.

Whatever the scenario is, it is well established today that life was largely present on the Earth 3.5 billion years ago, from the age of the oldest stromatolites (small geological structures resulting from the interaction of microorganisms with their environments). They also show that this was already a complex life, capable of photosynthesis. It is likely that the first living systems were simpler. The recent discovery of the catalytic properties of RNA and of an 'RNA World' suggests that these biomacromolecules may have been the first replicating system. However, many still doubt, because of the experimental difficulties in synthesizing prebiotically these molecules, and even their building blocks (the nucleotides). On the contrary, amino acids and their polymers are much easier to obtain. The question is still open.

If there is life elsewhere, there is no reason to assume that it must have the same appearance as life we know on Earth, because of the variety and diversity of terrestrial life at the morphological level. However, at the molecular level, the terrestrial example may be a more general one. The importance of liquid water and of the chemistry of carbon in the prebiotic terrestrial processes is probably not restricted to the Earth: water is an abundant molecule and carbon an abundant element in the universe. The discovery of an active organic chemistry in the interstellar clouds clearly supports the idea that organic chemistry is universal. It is thus reasonable to assume that extraterrestrial life is also based on carbon chemistry and liquid water, even if the hypothetical extraterrestrial biochemistry may not necessarily be identical to the one we know.

Exobiology in the solar system

Many objects of the solar system are of exobiological interest: not only Earth, but also comets, Mars, Europa, and even the giant planets and some of their satellites, such as Titan and Triton, because of the very complex organic chemistry which is involved in their environments.

Table 2. Characteristics of exobiologically important planets and satellites of the solar system.

Planet or satellite	Density ($g\ cm^{-3}$)	Distance to the sun (AU[a])	Mean surface temperature (°C)	Surface pressure (bar)	Atmosphere	
					Main composition	Organic compounds
Earth	4	1	22	1	N_2, O_2	Many
Mars	3.7	1.5	−50 to −70	0.007	CO_2, N_2	None
Jupiter		5	No surface tropopause: −255		H_2, He, CH_4 CH_4	Several hydrocarbons
Europa	3	5	−150 to −180		Negligible	No but possibility of subsurface liquid water
Saturn		10	No surface tropopause: −190		H_2, He, CH_4	Several hydrocarbons
Titan	1.9	10	−180	1.5	N_2, CH_4	Several hydrocarbons and nitriles
Neptune			No surface tropopause: −220		H_2, He, CH_4	Several hydrocarbons, HCN
Triton			−235	14×10^{-6}	N_2	Methane

[a] 1 UA $\approx 150 \times 10^6$ km.

Meteorites, micrometeorites and comets

Until 1969, the only extraterrestrial samples available in our laboratory were METEORITES, in particular carbonaceous CHONDRITES. The detailed study of meteorites has not revealed the presence of extraterrestrial microorganisms in those objects. The recent story of the Martian meteorite ALH 84001 does not undermine this statement. However, it is now fully established from careful chemical analysis of carbonaceous chondrites that this class of meteorites is rich in organic compounds. The several per cents of carbonaceous matter includes molecules of biological interest, such as amino acids and even nucleotide bases. Furthermore, the recent re-analyses of some of these meteorites shows the presence of an excess of L enantiomers in the amino acid content of extraterrestrial origin. This should have a strong input on our understanding of the origin of chirality in the terrestrial living systems. COMETS may have also played a major role in the origin of life on Earth, by importing water and organics on primitive Earth. In any case, they are important objects for exobiology because of the cometary organic chemistry. Although the molecular composition of the cometary nucleus is still not known today, comets are assumed to be very rich in organics, made of C,H,O and N atoms. The future cometary missions, in particular the ESA Rosetta mission with *in situ* analysis of the cometary nucleus, should provide in the first decade of 2000 essential information on the cometary nucleus.

Mars and Europa

Thus far, two planetary objects seem to be the most promising for a direct search for extraterrestrial life in the solar system. The first is the planet MARS and the second is EUROPA, one of the Galilean satellites of Jupiter.

In spite of its dimensions (about half of the Earth) and the absence—now—of a dense atmosphere and of liquid water, Mars is still considered as the best target. VIKING has not been able to detect the presence of microorganisms (autotrophs or heterotophs, see the definitions above) in the Martian soil. However, it has shown that the red planet was probably covered by liquid water and had a dense atmosphere at the time life had already emerged on Earth. Since, at that time, the Earth and Mars were very similar, it is logical to assume that what occurred on the Earth also occurred on Mars. Then both planets have evolved differently. Because of a tectonic activity too light to recycle carbon dioxide (essential for keeping the surface warm by the greenhouse effect), Mars lost most of its atmosphere and became colder and colder. It also lost its liquid surface water, which may now be trapped as a solid 'permafrost' in the Martian soil. Also, under such conditions, the atmosphere became strongly oxidizing; the oxidants, such as hydrogen peroxide, diffused in the soil, and all Martian life gradually disappeared from this hostile

environment, at least on and near its surface. Although the presence of life as extant on Mars is not fully excluded, future missions to Mars will have to embark scientific instrumentation to search for traces of extinct life in the Martian soil, and deep enough (at least a few meters deep) to reach depths where the oxidation processes are held to be negligible. Such missions are in preparation now.

The interest of exobiologists in Europa is more recent. VOYAGER data of the outer solar system have provided enough information to build models of the internal structure of many of the giant planets and their satellites. Among the three main models of Europa, one assumes that the icy surface of the Jovian satellite corresponds to a water ice crust several kilometers deep, covering an ocean of liquid water several tens of kilometers down. If such an ocean has hydrothermal activity, the presence of living organisms, prokaryotic microorganisms and even macroscopic eukaryotes, cannot be ruled out. However, the detection of such living systems will not be an easy task.

Titan

Another planetary object was examined by the Voyager mission and became, subsequently of prime interest for exobiology: TITAN. Voyager demonstrated that the largest satellite of Saturn, second by size in the solar system, has a dense atmosphere, mainly made of molecular nitrogen (more than 90%), with a noticeable concentration of methane (several per cent). Although Titan is much colder than the Earth, its atmospheric thermal profile is very similar to the terrestrial one, with a troposphere (95–74 K), a tropopause (74 K) and a stratosphere (74–170 K), owing to the presence of greenhouse gases (mainly methane and hydrogen) and antigreenhouse components (clouds and aerosols). Such a main chemical atmospheric composition is very favorable to organic syntheses. From laboratory experiments and theoretical modeling, one can expect many organics in Titan's atmosphere, mainly hydrocarbons and nitriles. Indeed, several organic compounds have already been detected: they all belong to the two classes of organics. Furthermore, the most important nitriles of terrestrial prebiotic chemistry—hydrogen cyanide, cyanogen and cyanoacetylene—have been detected in Titan's atmosphere. This environment is also very rich in aerosols and, probably, in clouds. Thus, it is also the only known satellite the surface of which is not visible from outside. Although the chemical nature of these aerosols has not been ascertained directly so far, it seems likely that they are mainly organic, with a nucleus of macromolecular nature. Furthermore, models of the surface and its interaction with the atmosphere strongly suggest that it is partly covered by seas and lakes of liquid methane and ethane (a necessary source and sink, respectively, of these two compounds on Titan).

With the exception of liquid water, absent on this too cold a planetary object, because of its environment, very rich in organics, in the gas and aerosol phases, and the possible presence of liquid bodies on its surface, Titan shows many similarities with primitive Earth. Studying Titan now should provide much key information on the possible couplings in the organic-related processes between the different parts of a planetary geofluid. Furthermore, study of Titan's chemistry, owing to the absence of liquid water, could also provide crucial data on the role played by liquid water in exobiology.

The Cassini–Huygens mission launched in October 1997 will reach the Saturn system in 2004 (see CASSINI MISSION). Then the Cassini NASA spacecraft will become an artificial satellite of Saturn and will release the Huygens ESA probe which will enter Titan's atmosphere. During 2.5 h of descent, the six scientific instruments aboard the probe will perform a detailed physical and chemical analysis of Titan's atmosphere (gas and aerosols) and surface. During the nominal duration of the mission (until 2008), the 12 scientific instruments of the Cassini orbiter will also provide essential information of exobiological importance on Titan's environment.

Exobiology outside the solar system

The interstellar medium

Organic chemistry is specific neither to the Earth nor to the solar system. It seems to be widely present in the whole universe. One hundred and ten different molecules have already been detected in the interstellar medium: a large majority of those (87) are organic (and only seven include silicon atoms). A complex organic chemistry probably occurs in interstellar clouds, in the gas and in the solid phase of the interstellar dust. Such chemistry may have also been involved in the molecular cloud from which the presolar nebula, and then the solar system, arose. Studying this chemistry and its evolution during the accretion phase of the presolar and the solar system is of great exobiological importance.

Extra-solar planets

Since the first—now confirmed—detection of a planet around the star 51 Peg by the Swiss astronomers Mayor and Queloz in 1996, more than a 20 EXOPLANETS have been discovered around close-by stars. Because of our current technologies, such discoveries are limited to Jupiter-size planets. However, they already show a wide variety of planetary objects in the universe, since the detected giant planets are very different from the solar system's ones, being much closer to their star and much warmer. There may be Titan-like satellites orbiting around these giant exoplanets having dense atmospheres, together, contrary to Titan, with liquid water. These planetary systems may also have Earth-like planets, which should be detectable with our future technologies. We should even be able to detect, by remote sensing, signatures of life on these hypothetical planets. Although this awaits confirmation, the presence of molecular oxygen in large abundance, and hence of ozone, in a planetary atmosphere may turn out to be a fair indication. Detection of intense infrared bands of ozone on an exoplanet should strongly suggest the presence of life on it.

Table 3. The main 'SETI' experiments carried out up to now (from J Tarter).

Year of the experiment	Observer(s)	Site	Target	Duration (h)
1960	Drake ('Ozma')	NRAO	2 stars	150
1964–1965	Kardashev and Sholomitskii	Crimea	2 quasars	80
1970–1972	Slysh, Pashchenko, Rudnitskii and Lekht	Nancay	5 OH masers	2
1979–1982	'Serendip' Team	California	Random	400
1981–1988	Biraud and Tarter	Nancay	343 stars	∼600
1990–	Colomb 'Meta II'	Argentina	Whole sky visible from Argentina	Permanent
1992–1993	'HRMS' NASA Team	Arecibo	25 stars	200
1992–	Bowyer, Werthimer and Donnelly ('Serendip III')	Arecibo	30% of the sky visible from Arecibo	50
1995	Phoenix Project	Australia	311 stars	2600

SETI

Another approach assumes that life has evolved, Earth like, toward intelligence and technologically advanced civilizations: we thus have to search for signals from such hypothetical extraterrestrial intelligence (SETI). As proposed by Cocconi and Morrison as early as in 1959, the radiowave domain seems to be the most appropriate for interstellar communications. Furthermore, there may be 'magic' wavelengths in the universe, corresponding to emission lines of very abundant compounds, such as the specific radio line of hydrogen at 21 cm. The first SETI experiment was carried out by Frank Drake in 1960 (see SETI INSTITUTE). With his project 'Ozma', he listened during several weeks to two nearby stars (Epsilon Eridani and Tau Ceti) at the magic wavelength of 21 cm. Since then, several tens of similar experiments have been performed, including recently, with a dedicated detector of several millions of channels. No clearly identified signal of extraterrestrial intelligence has been detected (yet). However, only a very small fraction of our universe has been explored thus far. Although we have not yet received any clear message from an extraterrestrial civilization, we have sent already several outward. The Pioneer X and XI spacecraft, launched in the early 1970s, which now travel outside the solar system, carry a metallic frame engraved with information on the solar system, the Earth and terrestrial life. Similarly, Voyager 1 and 2, launched in 1977, carry a videodisk about our planet. A message has also been sent from the Arecibo radiotelescope toward Messier 31. Of course, all these actions are only symbolic, but they clearly show that, today, the idea that there may be life elsewhere, including intelligent life, is largely accepted by the scientific community as well as the political community.

Current studies and prospects

Exobiology is present in every field and almost all exobiological approaches are effectively followed up to this day. A wide scientific community is working in the field of life origins, as demonstrated by the size (about 500 members) of the International Society for the Study of the Origin of Life (ISSOL). In this field, the likely future privileged studies will probably be the search for replicating molecules simpler than RNA, prebiotic syntheses in the submarine hydrothermal vents (through theoretical modeling as well as laboratory experiments) and studies on prebiotic processes from micrometeorites. The 2000 millennium will see a large increase of the exobiological explorations of the solar system. Many missions to Mars are already planned in the 2000–2010 period, with dedicated instrumentation to search for past and present life on the red planet. This period should also lead to important discoveries about comets, with the Rosetta missions, and about Titan, with Cassini–Huygens. We can even expect a mission to Europa, with a search for life in its hypothetical oceans. In the 2010–2020 period, if not before, one could expect, with a technology similar to the one planned in the IRSI (ex-Darwin) mission, the detection of Earth-like extrasolar planets and of extraterrestrial biological activity through the discovery of ozone. Whatever these discoveries, it is clear that the new millennium should drastically encourage multidisciplinarity. Exobiology, as one of the largest multidisciplinary fields, should thus, placed in the foreground, be the field of the future.

Exosat (European X-ray Observatory Satellite)

European Space Agency x-ray observatory launched in 1983. Designed to locate and identify cosmic x-ray sources. A highly elliptical 356 km × 191 581 km Earth orbit allowed continuous observations for up to 72 hours. Payload consisted of three instruments to study the x-ray spectrum between 0.04 and 50 keV. Suffered a number of equipment failures but made important studies of binary stars and galaxies, including discovery of several new transient x-ray sources. Operations ended April 1986.

Expanding Universe

A universe that expands with time. Although the possibility had been raised earlier through theoretical work carried out by Willem de Sitter (1872–1934), Aleksandr Friedmann (1888–1925), and the Abbé Georges Lemaître (1894–1966), that our universe is expanding was first demonstrated observationally in 1929 by Edwin P Hubble (1889–1953), through his measurements of the redshifts in the spectra of galaxies.

In our expanding universe, each galaxy (or cluster of galaxies) is receding from every other one, the speed of recession of one galaxy from another depending on the separation between them. If motions induced by local concentrations of mass are ignored, the galaxies and clusters behave as if they were at rest in an expanding space. A useful analogy is to consider the whole of three-dimensional space to be represented by the (two-dimensional) surface of a balloon and to represent galaxies and cluster by spots stuck to this surface. As the balloon expands, each 'galaxy' moves away from every other one but there is no unique center to this expansion (each dot is equivalent to every other one, and the *surface* of a balloon does not have a center).

Explorer

Series of small NASA experimental, scientific and research satellites. Explorer 1, launched in 1959, discovered Earth's van Allen radiation belts. They included the Interplanetary Monitoring Platforms (10 satellites which investigated the Earth–Moon magnetic environment over a complete solar cycle), the Radio Astronomy Explorers (Explorers 38 and 49) and the Small Astronomy Satellites (Explorers 42, 48 and 53). In March 1999, Explorers 50 (IMP 8) and 67–74 (EUVE, SAMPEX, RXTE, FAST, ACE, SNOE, TRACE and SWAS) were still operating. Of the 72 successful Explorer missions, five operated for 10 years or more. They include the ISEE 3/ICE spacecraft (14 years), the IUE spacecraft (19 years), and IMP 8 (still operational after 25 years). (See also INTERNATIONAL SUN–EARTH EXPLORER, DYNAMICS EXPLORER, UHURU.)

Extended Atmospheres

During a total ECLIPSE of the Sun, when the Moon blocks out the intensely bright disk of the Sun, a faint white 'halo' can be seen surrounding the Sun (see figure 1). This halo, officially called the Sun's 'CORONA' (i.e. 'crown'), exists mainly because there are electrons in the outer solar atmosphere: even though the disk of the Sun is hidden from direct view, the electrons scatter a fraction of the light from the disk towards our eyes. The fraction which is scattered towards us is small, typically no more than about 1 part per million of all the photons which emerge from the Sun. (Farther out from the Sun, there is also some scattering from dust particles.) The fraction of 1 in a million has to be compared with the sky brightness near the Sun due to the molecules and dust in our own atmosphere: at the best mountain observing sites on Earth, the intensity of pure blue sky may be low enough that the innermost corona is just visible to the naked eye. More typically, the brightness of clear sky near sea level is a thousand times brighter than the corona. This explains why the corona is too faint to be seen by the eye outside of eclipse. But when the corona *can* be seen, it may be quite irregular in shape, extending in certain directions much more than in others. The minimum extent of the corona is over the North and South poles of the Sun, especially when the Sun is close to the minimum level of SUNSPOT activity. The greatest extent of the corona occurs in features called 'streamers', which can be seen to distances of as much as a solar radius or more beyond what is usually thought of as the 'edge' of the Sun.

Also visible for a short period of time during certain phases of a total eclipse is a rose-colored aureole of light close to the Sun (see figure 2). This colored aureole, known as the 'CHROMOSPHERE' (i.e. 'color sphere'), also extends out beyond the usual 'edge' of the Sun, although not as much as the corona.

Together, the chromosphere and the corona constitute what may be called the 'extended atmosphere' of the Sun. It is now known that such extended atmospheres also exist around other stars.

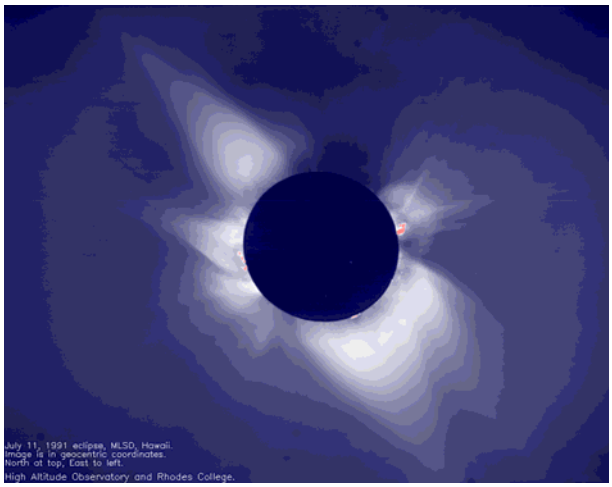

Figure 1. The solar corona: an irregular halo of light which can be seen by the naked eye during an eclipse of the Sun. The image was obtained by observers from the High Altitude Observatory and Rhodes College on 11 July 1991.

Figure 2. The solar chromosphere: a narrow band of reddish light which can be seen briefly by the naked eye close to the edge of the eclipsed Sun.

The non-extended case

In order to appreciate the significance of *extended* atmospheres in the Sun and other stars, it is instructive first to discuss atmospheres which can be referred to as 'non-extended'. This discussion will serve to highlight the conditions which must be satisfied in order that a star may develop an atmosphere which can be truly be referred to as 'extended'.

Two objects which are prominent features in the sky appear to have sharp edges: the Moon and the Sun. This seems like a trivial observation, but it tells us something informative. As far as the Moon is concerned, it is hardly surprising that we see a sharp edge at all times: after all, the Moon is made of solid material, solid enough that twelve men have walked on its surface. When we look at the edge of the Moon, we are viewing a region where the solid surface stops, and the vacuum of space begins. Since this is a discontinuous transition, it is no wonder that the edge appears sharp to us. But the Sun does not have a solid surface: it is composed of gas, which tends to diffuse out in all directions. Shouldn't this cause the 'edge' of the Sun to appear fuzzy? And yet the Sun appears to have a sharp edge: when you watch the Sun setting, there comes a moment when the last sliver of the solar disk is just visible, and then, in an instant, it disappears from view.

Why does the edge of the Sun seem sharp? The reason has to do with the fact that the light we see when we look at the Sun comes from gas which is not entirely free to diffuse wherever it wants to go: the force of *gravity* holds on to the gas. If gravity had its way, it would drag all of

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the gas down into the center of attraction at the center of the Sun. But gravity does not have its way: the inward force of gravity is balanced by the pressure which the gas exerts. Gas pressure arises from the fact that the individual atoms are not bound tightly together, but are free to move in all directions. Because of this freedom of movement of its constituent particles, a gas has a natural tendency to want to diffuse away and fill all available space.

Under some conditions, the opposing tendencies of gravity and pressure can come into balance with each other, and the gas can remain stationary. But it is sometimes impossible to find a balance between gravity and pressure: in such a case, the gas cannot be stationary. Both of these cases apply in different parts of the solar atmosphere, and they help us understand why the Sun has a non-extended atmosphere in one region and an extended atmosphere in another region.

Hydrostatic equilibrium

When the attractive force of gravity is in exact balance with the tendency of gas to diffuse, the gas is said to be in 'hydrostatic equilibrium' (HSE). The equation which describes HSE can be derived by requiring that when an extra parcel of gas is added to the atmosphere, the extra weight of that parcel must be balanced by extra pressure. The equation which describes this balance is

$$\frac{\mathrm{d}p}{\mathrm{d}r} = -g\rho \tag{1}$$

where p is the gas pressure, r is the radial distance from the center of the Sun, g is the acceleration due to gravity and ρ is the gas density.

A particularly simple solution of the HSE equation can be obtained if we consider the special case of a perfect gas at a uniform temperature. In such a gas, the pressure exerted by the gas is related to the density of the gas according to Charles' law:

$$p = \frac{R_g \rho T}{\mu}. \tag{2}$$

Here, T is the temperature of the gas (on an absolute scale), μ is the mean molecular weight of the gas (on a scale where a hydrogen atom has a weight of unity), and R_g is referred to as 'the gas constant'. The value of R_g is defined as the ratio of Boltzmann's constant to the mass of a hydrogen atom: R_g ($\approx$8.3 J mol^{-1} K^{-1}) is a measure of the energy in the random (thermal) motions of 1 g of hydrogen atoms at a temperature of 1 K above absolute zero.

Inserting equation (2) into equation (1), and assuming for the moment that g and μ are also constant, we can solve for density ρ as a function of radius r:

$$\rho = \rho_0 \exp[-(r - r_0)/H]. \tag{3}$$

Here, ρ_0 is the density at the level in the atmosphere where the radial distance equals r_0. The quantity H, which has the dimensions of length, is related to the parameters of the atmosphere by the expression

$$H = \frac{R_g T}{g\mu}. \tag{4}$$

To see the significance of the length H, note that when we measure the density of the gas at a height H above $r = r_0$, equation (3) tells us that the local density is smaller than the density at $r = r_0$ by a factor e. Every time we move up by a *linear* distance H, the density falls off by a *multiplicative* factor e. Thus, if we move up to a height of $10H$ above r_0, the local density will be smaller than at $r = r_0$ by a factor of e^{10}, i.e. by a factor of about 22 000. This means that, for every 22 000 atoms at $r = r_0$ there is only about one atom at $r = r_0 + 10H$. Another way of looking at this is to consider that, of 22 000 atoms at $r = r_0$, all of which have a tendency to diffuse outwards into space, only one has enough energy (i.e. fast enough speed) to climb up against gravity to heights of $10H$ above r_0. The number of atoms which are able to climb up to even greater heights (say, $20H$) is even smaller (by a further factor of 22 000). Clearly, the number density of atoms falls off very rapidly with increasing height in this example of HSE.

The quantity H, which measures how rapidly the density falls off with height, is referred to as the 'scale height' of the atmosphere. Physically speaking, a significant role for the scale height has to do with the amount of gas in the atmosphere: if all the gas in an atmosphere were forced to have the same density, then the thickness of the atmosphere would be equal to H. That is, if I imagine that I am standing at a region in the atmosphere where the local number density of the gas is n_0, then the total number of particles lying in a column of area A above my head equals n_0 times H times A. This result will be useful below when we estimate the number density of particles in the corona.

Now that we have an expression for H, we can understand why the edge of the Sun is sharp: it has to do with the numerical value of H in the layers of the solar atmosphere that we can see with our eyes.

The scale height in the solar photosphere

The layers of the Sun which we can see are called the 'SOLAR PHOTOSPHERE' (literally, the 'light-sphere'): these layers contain the atoms of gas which scattered the photons of light for the last time before the light started on its journey through the (relative) vacuum of interplanetary space towards our eyes. Gas in the photosphere has a temperature T of about 5000 K. Moreover, the gas consists of about 90% neutral hydrogen atoms and about 10% helium: this leads to $\mu \approx 1.3$. The acceleration due to gravity in the photosphere g_{phot} can be estimated from Newton's formula $g_{\mathrm{phot}} = GM_\odot/R_\odot^2$, once we know the mass of the Sun $M_\odot \approx 2 \times 10^{30}$ kg and the radius of the photosphere $R_\odot \approx 7 \times 10^8$ m. ($G \approx 6.67 \times 10^{-11}$ N m^2 kg^{-2} is Newton's constant of gravitation.) Inserting the above values, we find $g_{\mathrm{phot}} \approx 270$ m s^{-2}.

Now we are in a position to evaluate the scale height H_{phot} in the photosphere: $H_{\mathrm{phot}} \approx 120$ km.

The 'edge' of the photosphere: how sharp is it?

Suppose I point a telescope at the edge of the Sun and line up a cross-hair exactly with the photosphere. The density

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of the gas there has a certain value, ρ_0, and this is enough to scatter the photons from the Sun for the last time and make the photons come towards me. I measure the intensity of the light by counting how many photons come into my detector every second from this first pointing, P_1. Now suppose I offset the pointing of the telescope to a second position: I set the cross-hairs on gas which lies 1200 km above the photosphere. The density of the gas at this new position, which is $10H_{\rm phot}$ above the first position, is 22 000 times less than at the first position. With such a low density, there will be roughly 22 000 less scatterings occurring, and as a result, the number of photons I will count from this second pointing P_2 will be less than P_1 by 22 000. Since P_2 is so much less than P_1, the gas at pointing 2 appears dark in comparison to the photosphere. Thus, in moving from P_1 to P_2, I have moved from bright sunlight into what is essentially darkness: by all definitions, I have moved past the 'edge' (or limb) of the Sun.

Now in the context of how sharp the edge of the Sun appears to us, the question is: how far, in angular terms, did I have to offset the telescope to go from pointing 1 to pointing 2? The answer depends on the distance to the Sun. This is known to be about 150 million km. At such a distance, in order to shift a telescope cross-hair a distance of 1200 km, I must move the telescope through an angle of between 1 and 2 arcseconds. The human eye cannot resolve such a small angle (as small as a golf ball seen from a distance of a few miles). As a result, when I look at the edge of the Sun, I see the Sun going from bright (photosphere) to dark (gas at a height of $10H_{\rm phot}$) within an angular distance that is so small that I cannot resolve it. The edge of the Sun therefore *appears* essentially discontinuous to me even though, in principle, the gas density actually falls off smoothly and continuously according to the predictions of HSE.

The chromosphere

During an eclipse, when the chromosphere appears above the edge of the Moon, the light comes mainly from spectral lines emitted by hydrogen (see HYDROGEN SPECTRUM). The strongest of these in the visible spectrum is referred to as Hα. The wavelength of Hα is 6563 Å, which is in the red region of the spectrum. It is the predominance of this line that gives the chromosphere its reddish color. Careful measurements of the way in which the intensity of Hα and other spectral lines varies with height enable observers to determine a 'scale height' for each line: this is the height over which the intensity of the line falls off by a factor of e. Different lines yield somewhat different results, but average values are many hundreds of kilometers, or even 1000 km.

Although a model is required in order to interpret strictly the intensities of spectral lines in terms of local gas densities, the data indicate that scale heights in the chromosphere are certainly larger than $H_{\rm phot}$. Hydrostatic equilibrium, where $H = R_g T/g\mu$, is a good approximation for the chromosphere, and as a result, the chromosphere requires temperatures which are hotter than in the photosphere. The excess temperature in the chromosphere compared to the photosphere is required to be a few thousand degrees.

The corona: what are the temperatures?

The image of the corona in figure 1 indicates that the corona extends in certain directions to an appreciable fraction of a solar radius before fading out. Measurements of the way in which the brightness fades out can be used to assign also a 'scale height' $H_{\rm cor}$ to the density of the coronal material. Typical values of $H_{\rm cor}$ are one or two tenths of a solar radius, i.e. $H_{\rm cor} \approx 10^8$ m. This is almost 1000 times larger than the scale height in the photosphere.

This factor of almost 1000 indicates that the Sun truly does have an outer atmosphere which is 'extended' compared to what we see in the photosphere.

Does hydrostatic equilibrium apply to the corona? The answer depends on what part of the corona one is discussing. First, let us discuss regions close to the Sun, within a few tenths of a solar radius of the photosphere. (We will return in the next section to regions farther out.) Close to the Sun, HSE is probably a good approximation. Therefore, in order to reproduce a coronal scale height $H_{\rm cor}$ which is almost 1000 times larger than in the photosphere, we need to have a coronal temperature which is almost 1000 times as large as in the photosphere. That is, the coronal temperatures must be a few million degrees.

Can this be true? Can gas in the extended solar atmosphere really be almost 1000 times hotter than the gas in the photosphere? The answer is: yes! The surest proof that such hot gas is present is provided by instruments which detect x-rays from the Sun. An example is shown in figure 3. This image was constructed by the Soft X-ray Telescope (SXT) on board the YOHKOH spacecraft. SXT responds mainly to photons which are emitted by gas at temperatures of 2–3 million K. The SXT image shows that the corona does not emit uniformly: there are bright spots (where photon intensity is large) and dark spots (the so-called 'coronal holes') where photon intensity is so low that the detector records 'nothing'. In the dark 'coronal holes' (e.g. near the bottom of the image in figure 3), we can see the circular outline of what our eyes see when we look at the Sun: the photosphere. Our eyes are sensitive to photons with wavelengths of a few thousand Å, and in such wavelengths, the photosphere of the Sun (with its temperature of about 5000 K) is very intense. That is why the Sun (or more strictly, its photosphere) appears so bright to our eyes. But the detectors in SXT are looking for photons with wavelengths of a few Å: the photosphere emits very few of these, and as result, SXT 'sees' the photosphere as a dark object.

The brightest features in the SXT image are compact regions where a trained eye can see so-called 'CORONAL LOOPS': these appear as partial arcs of circles that start at one position on the surface of the Sun, loop upward to a certain height, and then return to the solar surface. When images of the Sun in x-rays are compared with magnetic field data, it is found that the x-ray loops are associated with regions

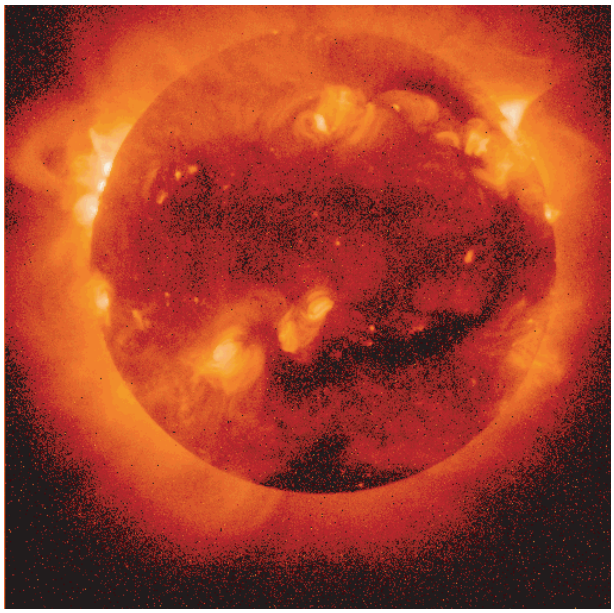

Figure 3. The Sun as seen in x-rays: the image was obtained by the Soft X-ray Telescope on board the YOHKOH satellite in April 1999.

of strong magnetic field. Each loop rises out of a region where the magnetic field has one polarity (say northward), and returns to the Sun in a region of the opposite polarity.

The discovery that magnetic fields serve to organize the structure of the solar corona was a key step in astronomers' attempts to understand how the gas in the corona can be heated to temperatures of almost 1000 times the photospheric temperature. In the 'CORONAL HOLES' , magnetic field lines are open into interplanetary space: ionized gas is free to stream out along these open field lines. The essential difference between coronal regions which are dark in x-rays and those which are bright in x-rays has to do with the magnetic field topology: the fields are open or closed (respectively) in dark or bright regions of the corona.

The corona does not have a unique temperature. In active regions, some material may reach temperatures $T_{\max}$ as high as several million degrees. In the quiet sun, $T_{\max}$ may be only 1–2 million degrees. In the flaring Sun, $T_{\max}$ may be several tens of millions of degrees. But in all cases, there are also measurable quantities of gas with temperatures below $T_{\max}$: in fact, by observing the Sun in spectral lines which are formed at a variety of temperatures, one can determine how much gas is present at various temperatures. The distribution of material at various temperatures is called the differential emission measure (DEM). Typically, the shape of the DEM is a power law with positive slope between temperatures of the order of 10^5 K and $T_{\max}$. Below 10^5 K, the DEM has a negative slope. Detailed study of the shape of the DEM may eventually allow one to infer something about the physical nature of the mechanism which is responsible for heating the corona.

The corona: what are the densities?

Now that we know the scale height $H_{\rm cor}$ in the low corona (where HSE applies), we can use the observed brightness to estimate roughly the density of the material at the base of the corona, $n_{\rm cor}$ electrons m^{-3}. To do this, let us imagine what happens to photons which emerge from 1 m^2 of the solar photosphere during an eclipse of the Sun. These photons stream away from the Sun, mostly along the radial direction, and by the time they have passed through the corona, the total number of electrons $N_{\rm e}$ which they have passed by in their 1 m^2 column is $n_{\rm cor} \times H_{\rm cor} \approx 10^8 n_{\rm cor}$. There is a finite probability $p_{\rm es}$ that, when a photon passes by an electron, the photon will be scattered: the quantity which determines $p_{\rm es}$ is the so-called Thomson cross-section, $\sigma_{\rm e}$ which is about 10^{-28} m^2. (The value of $\sigma_{\rm e}$ a few times $\pi r_{\rm e}^2$ where $r_{\rm e}$ is the classical radius of the electron: $r_{\rm e} = {\rm e}^2/mc^2$. Here, e and m are the charge and mass of the electron, and c is the speed of light.) The probability that a photon will scatter after passing through $N_{\rm e}$ electrons cm^{-2} is $p_{\rm es} \approx N_{\rm e} \times \sigma_{\rm e}$. Inserting the above values, we find that

$$p_{\rm es} \approx 10^{-20} n_{\rm cor}. \qquad (5)$$

Now the observed intensity of the corona is about 10^{-6} times the photospheric intensity. This indicates that $p_{\rm es}$ has an empirical value of order 10^{-6}. Referring to equation (5) above, we see that $n_{\rm cor}$, the electron number density in the low corona, must be of the order of 10^{14} m^{-3}. Since the major constituent of the Sun is hydrogen, the most abundant element in the corona is also hydrogen. In the photosphere, hydrogen exists in a form which is almost entirely electrically neutral, with one electron bound to each proton. In the corona, the temperature is high enough to ionize the hydrogen essentially completely: for each free electron, therefore, there is also one free proton.

Breakdown of hydrostatic equilibrium: 'super-extended' atmosphere

We mentioned above that in the low-lying parts of the solar corona, hydrostatic equilibrium (HSE) is probably satisfied. But once we admit the existence of gas at temperatures of a million degrees of more, the assumptions of HSE eventually break down. To see why this is so, we return to equation (1). So far, we have treated the gravitational acceleration g as a constant: this is a good approximation as long as we are considering gas within a few scale heights of the photosphere. (The value of g at a radial distance of $r = R_\odot + 10H_{\rm phot}$ differs from that at $r = R_\odot$ by only a few tenths of 1%.) But when we consider things on a larger scale, g can no longer be regarded as constant: at a radial distance r from the Sun, we need to use the local value of g, i.e. $GM_\odot/r^2$. This changes the solution of equation (1) in a fundamental way. Inserting the radially varying g into equation (1), and again assuming for simplicity that the gas has a unique

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

temperature, we find that the solution now takes on a strikingly different form:

$$\rho = \rho_0 \, \mathrm{e}^{\{[A(r_0/r-1)]\}}. \tag{6}$$

Here, $A = GM_\odot \mu / R_g T r_0$ is a measure of how effectively the thermal pool fills up the Sun's gravitational well. Equation (6) describes how the density in the solar corona would behave if the corona were in hydrostatic equilibrium. A remarkable feature of the density distribution in equation (6) is that as we move farther and farther from the Sun, i.e. as r tends to infinity, the density of the coronal material does *not* fall to zero. Instead, the density approaches a constant value: $\rho(\infty) \rightarrow \rho_0 \, \mathrm{e}^{-A}$.

Inserting $T = 10^6$ K, and use the solar parameters mentioned above (except that $\mu \approx 0.5$ in fully ionized hydrogen), we find $A \approx 12$. Now, as we have seen, the gas at the base of the solar corona has a number density of some 10^{14} protons m^{-3}. At infinity, a corona in hydrostatic equilibrium would have a number density which is less than this by e^{-12}, or 6×10^{-6}. Thus, the number density of the solar corona at infinity would be about 6×10^8 protons m^{-3}. Such a density is much larger than the density of gas in the interstellar medium (ISM): the latter contains typically 10^6 protons m^{-3}.

Because the ISM has a density (and pressure) which is many times smaller than the corona in hydrostatic equilibrium, it is impossible for the ISM to contain the corona: the latter has a pressure which is too high to be confined.

What happens when HSE breaks down? To answer that, we note that the equation of HSE is itself only a special case of a more general equation which describes the law of conservation of momentum. For a gas of density ρ moving radially outward at speed v, the momentum per unit volume is ρv. Conservation of momentum for this gas is described by the equation:

$$\rho \frac{\mathrm{d}v}{\mathrm{d}t} = -\frac{\mathrm{d}p}{\mathrm{d}r} - \rho g + F \tag{7}$$

where F is a general symbol for any other forces which may be present in the corona apart from pressure and gravity. (Magnetic fields can give rise to extra forces which are important for the corona.) In the case where $F = 0$, and HSE is satisfied (see equation (1) above), the right-hand side of equation (7) is exactly zero, and equation (7) can be satisfied by the solution in which the gas does not move, $v = 0$: the absence of motion justifies the term 'static' in 'hydrostatic equilibrium'. But if pressure forces do not balance gravity, then the right-hand side of equation (7) is non-zero. As a result of the unbalanced forces, the gas begins to accelerate in response to Newton's famous second law of motion. Instead of hydro-'static' conditions, we now have to deal with unbalanced forces (i.e. dynamics). The onset of acceleration in the radial direction means that the corona must expand. This expansion of the coronal gas gives rise to a flow which is named the 'SOLAR WIND'.

It is important to note that when we talk of the solar wind, we are *not* talking about evaporation, as if a small fraction of the coronal material were 'boiling off': there is nothing evaporative about the process described by equation (7). The solar wind involves a truly hydrodynamic expansion *of the entire corona* (see also SOLAR WIND: CORONAL ORIGINS).

In the simplest case of steady flow, the velocity of outflow v does not depend on the time, but varies with radial distance. In this case, equation (7) can be written in the form

$$v \frac{\mathrm{d}v}{\mathrm{d}r} = -\frac{1}{\rho}\frac{\mathrm{d}p}{\mathrm{d}r} - \frac{GM_\odot}{r^2} + F. \tag{8}$$

The details of how rapidly the wind accelerates, i.e. the shape of v as a function of radial distance r, depend on the temperature (which controls the pressure) and especially on the nature of any extra forces F. But regardless of the details of F, we expect that at great distances from the Sun, all terms on the right-hand side of equation (8) will become small. This means that $\mathrm{d}v/\mathrm{d}r \rightarrow 0$ at great distances from the Sun. In other words, v tends to a constant value (the terminal speed) far from the Sun. The value of the terminal speed depends on where on the Sun the wind originates: empirically, wind from the polar regions of the Sun is found to have the highest terminal speed, some 700–800 km s^{-1}. The slowest observed wind speeds (about 300 km s^{-1}) are found to originate in streamers which are more common near the Sun's equatorial regions. The differences between winds from different locations on the Sun arise at least in part from differences in the forcing term F in equation (8). Over the polar coronal holes, waves on the magnetic field may help to provide momentum and energy to the wind.

The solar wind extends far beyond the visible edge of the Sun, far beyond even what the eye sees during an eclipse: in fact the wind expands past the orbit of the Earth, and past the orbits of all of the known planets. No-one yet knows for sure how far out the wind expands. The most remote spacecraft which have been able to sample the wind (Voyagers 1 and 2), are at the time of writing (April 1999) about 50% farther from the Sun than Pluto's mean distance, and they still see the solar wind expanding. Some theories make predictions about where the solar wind will be stopped by running into the ISM: but the Voyagers have not yet reached such a point (see VOYAGER MISSION).

The fact that the solar corona extends throughout the solar system gives a new twist to the definition of 'extended atmosphere': it can come as a shock when one first realizes that the Earth on which we live is itself embedded in the Sun's (super)-extended atmosphere.

Mass flux carried by the solar wind

How much mass does the solar wind carry away from the Sun? Spacecraft measurements of the solar wind as it passes Earth's orbit indicate that the mean solar wind density is some 5–10 $\times$ 10^6 protons m^{-3} while the mean velocity is 300–400 km s^{-1}. These measurements indicate that the Sun loses mass at the rate of a few million tons per

second. This is comparable to the rate at which mass is lost in the core of the Sun due to thermonuclear reactions. If the Sun has lost mass at a constant rate during its evolution (lasting some 10^{17} s so far), the wind has not caused any significant alteration to the mass of the Sun during its life: the change in mass is no more than 0.1%.

Other stars

The existence of chromospheres on stars of spectral classes G, K and M has been known for decades: the chromospheres reveal their existence in the form of emission lines of hydrogen and other elements in the spectrum.

Since about 1980, when the first x-ray telescopes on spacecraft with enough sensitivity to detect stars became operational, it has been discovered that stars of almost all types emit x-rays. The strongest sources of x-rays among single stars occur in dwarfs of spectral class M: some M dwarfs emit almost 1% of their entire luminosity in the form of x-rays. Compared to the Sun (where the x-ray output amounts to only one part in 10^5 or 10^6 of the entire luminosity), M dwarfs are truly efficient generators of coronae. Moreover, the coronae in M dwarfs contain components which are much hotter than in the Sun: the x-rays from certain M dwarfs require source temperatures of several tens of millions of degrees. In the Sun, temperatures as high as this are achieved only temporarily in short-lived explosions (flares). On the basis of data from the ground, it has been known for decades that M dwarfs are sites of large flares and strong magnetic fields. It seems likely that the strong heating of their coronas is connected to magnetic activity.

Cool giant stars exhibit evidence of chromospheric material, but not of coronal material. In such stars, there are, however, comparatively dense but comparatively slow winds, with mass loss rates which exceed the solar wind value by several orders of magnitude. These winds can be considered as extended atmospheres of such stars: although the photosphere of Betelgeuse (a red supergiant) has dimensions of a few hundred solar radii (i.e. a few AU), emission from the wind in certain lines can be traced out to distances of the order of 10 000 AU.

What heats an extended atmosphere?

As we have seen, the presence of an extended atmosphere depends on excess temperatures. What causes this excess heating? Attempts to answer that question have attracted a lot of attention in the course of the past few decades. The quest for an answer comes down to identifying a source of mechanical energy which can do work on the gas.

As far as chromospheric heating is concerned, a consensus seems to be emerging: acoustic waves from turbulent convection beneath the photosphere can heat at least the lower regions of the chromosphere. As these waves propagate upwards in the atmosphere, reaching gas of progressively lower density, the pressure fluctuations of the acoustic waves grow in intensity until shock waves are formed. The shocks cause localized heating of the gas, enough to reproduce many of the observed features of chromospheric emission. Dissipation of the waves is severe enough that in the Sun, almost no waves survive even as far as the upper chromosphere. In other stars, generation of acoustic waves by their convection may in some cases (especially M dwarfs) have properties which are more favorable to the survival of acoustic waves in the upper chromosphere: in such stars, the acoustic waves with longest periods may even help to provide some heat to the low corona.

In the chromosphere, the deposition of mechanical energy is balanced by radiation in spectral lines of abundant elements in certain stages of ionization. As long as these lines remain available for radiation, deposition of energy does not necessarily result in severe local heating: the deposited energy may simply be radiated effectively by slight increases in temperature. As a result of this competition between gain of energy and loss by radiation, the chromosphere on average may contain one or more regions where the temperature remains almost constant with increasing height. These temperature 'plateaus' may occur between about 6000 K and 20 000 K. The process of hydrogen ionization also serves to absorb mechanical energy without having the local temperature increase significantly: as a result, the average chromosphere in the Sun displays the remarkable property that the mean proton density remains essentially constant (within a factor of ± 2) over a range of altitudes where the mean hydrogen atom density falls off by a factor of 10^4. But overall, there is on average an inexorable rise in temperature with increasing height, and each of the elements becomes progressively more ionized. Eventually, one reaches a height where the temperature is such (between 10^4 K and 10^5 K) that *none* of the abundant elements is in stages of ionization where strong spectral lines are available. In such conditions, addition of extra mechanical energy inevitably causes the temperature to climb rapidly to millions of degrees. This rapid transition to coronal temperatures occurs over a narrow range of altitudes.

As regards coronal heating, magnetic effects must dominate in the source of mechanical energy. One widely discussed candidate is waves which propagate along the magnetic field: these waves can dissipate their energy in a variety of ways. For example, in active regions, a magnetic loop may act as a sort of resonant cavity which the wave can cause to 'ring' in such a way that the wave energy is deposited in the loop. And in coronal holes, waves on the magnetic field may dissipate and deposit both momentum and energy into the coronal gas. In active regions, miniature magnetic explosions ('nano-flares') may be occurring often enough that they can keep some closed magnetic loops hot.

Data from the SOHO spacecraft may help to pin down the mechanism which cause coronal heating. For example, there is already evidence that in coronal holes the coronal heating mechanism heats protons more efficiently than it heats electrons. And heavy ions (such as oxygen) are heated even more than protons.

Extragalactic Astronomy *c.*1900–1950

In 1931 the Dutch astronomer WILLEM DE SITTER (1872–1934) declared that 'Never in all the history of science has there been a period when new theories and hypotheses arose, flourished, and were abandoned in so quick succession as in the last fifteen or twenty years'. de Sitter was looking back on a period of turmoil and upheaval in the physical sciences, in which perhaps most importantly for astronomers the long-standing debate on the nature of NEBULAE had been settled and in which the entirely unexpected expansion of the universe had been proposed and widely accepted. These two epoch-making developments were due mainly to astronomers who in the first three decades of the 20th century made observations with giant optical telescopes of a class of nebulae, the spiral nebulae, which, it would become generally accepted after the mid-1920s, were galaxies. In fact, in these three decades extragalactic astronomy, as astronomers later would understand it, was established. This new field was in many ways a distinctly American activity—in considerable part because it was in the United States that the most powerful telescopes and the best-equipped astrophysical observatories were to be found, together with a sizable body of well-trained astrophysicists interested in problems of the nebulae.

Early history

The 18th and 19th centuries had seen wide ranges of opinion on the nature of the nebulae, the two most extreme being that all nebulae are star systems external to our Galaxy, so-called 'island universes', or that all the nebulae are indeed truly nebulous. However, by the end of the 19th century it had become widely accepted that none of the visible nebulae was an external galaxy. External galaxies might exist, but if so they lay beyond the reach of even the most powerful telescopes.

Three main pieces of evidence were reckoned by most astronomers to tell heavily against the island universe theory: (1) the distribution of the nebulae (it was generally agreed that the nebulae very largely avoid the plane of the Milky Way but, if the nebulae were truly independent galaxies, why should their position be correlated with our own Galaxy's orientation?), (2) the well-established gaseous nature of some nebulae and (3) the 'nova' of 1885 (now accepted to have been a supernova) that had flared in the heart of the Andromeda nebula. (The nova had reached a luminosity of about 1/10th of the entire nebula. How, astronomers asked, could a single star rival the brightness of a vast assembly of stars? Their answer was that it could not. The nebula was not a vast stellar assembly.)

At the start of the 20th century, most astronomers also judged the vast majority of nebulae to be 'spiral nebulae', that is, to exhibit a spiral shape. Lord ROSSE and the Parsonstown observers in the middle of the 19th century had been the first to discern the spiral form of a number of nebulae, but in the late 1890s JAMES E KEELER (1857–1900), while photographing nebulae and star clusters with the 36 in Crossley reflector at Lick Observatory in California, recorded vastly more spirals on his plates than he had expected; in fact, he reckoned, 120 000 of them were within reach of his telescope. In 1899 the German astrophysicist Julius Scheiner (1858–1913)—working at Potsdam, the leading German center for astrophysics—detected absorption lines in the spectrum of the largest, and so presumably one of the nearest, spirals, the Andromeda nebula. As it was well-known that the spectra of star clusters exhibited absorption lines, Scheiner contended that the Andromeda nebula itself was a star system that lay beyond the Galaxy. At first Scheiner's arguments won few adherents since nearly all astronomers were convinced that spiral nebulae developed into either single stars or sparse clusters. However, around 1910 a few investigators started to challenge this position. Led by E A Fath at Lick and Max Wolf at Heidelberg, they extended Scheiner's researches on the spectra of spirals and found that while some spirals displayed bright lines—well known by this time to be characteristic of gas clouds—most of those examined had spectra dominated by dark absorption lines. Perhaps, after all, some astronomers decided, the spirals are clusters of stars, maybe even distant galaxies.

During the 1890s Keeler had measured the shifts of the spectral lines of a number of planetary nebulae and, interpreting the shifts as Doppler shifts, he had determined their radial, or line-of-sight, velocities. They had radial velocities, on the whole, a little higher than, but essentially similar to, those of the stars. The measurement of the radial velocity of a spiral proved a much more daunting problem because of the low surface brightness of the spirals, but in 1913, V M SLIPHER (1875–1969) of Lowell Observatory in Arizona argued that the Andromeda nebula was rushing towards the Sun at 300 km s^{-1}, the highest speed then recorded for an astronomical body. Slipher's find was so puzzling that a few suspected its correctness. Doubts were, however, swiftly dispelled when others confirmed Slipher's result and Slipher himself obtained similar values for further spirals.

The observations of the spectra of spirals had persuaded some astronomers that the spirals were, or might well be, external galaxies, and the measured radial velocities won still more to this view. The velocities were so much higher than those of the confirmed members of the Galaxy that some astronomers decided that the spirals could not be a part of the same dynamical system. One result was that, by the mid-1910s, the island universe theory, a theory that a decade or so earlier had been almost completely out of favor, had become a leading topic of debate.

The shift of opinion about external galaxies had also been influenced by two other factors: (1) the wide-spread suspicion that the Galaxy itself has a spiral structure and (2) the 'grandeur' of the island universe theory. In 1911, for example, the brilliant English astrophysicist A S EDDINGTON (1882–1944) had declared that the island universe theory 'opens up to our imagination a truly magnificent vista

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of system beyond system—of universe beyond universe'. The theory's appeal to the scientific 'taste' of astronomers alone had, nevertheless, not been enough: the shift in opinion about external galaxies had also required the hard evidence of the spectrum and radial velocity observations of the spirals.

Novae in spirals

In 1917 astronomers found more evidence that bore on the debate about nebulae when NOVAE were detected serendipitously in a number of spirals. The first were found by H D CURTIS (1872–1942), an astronomer at the Lick Observatory, and a similar discovery was made shortly after by G W RITCHEY at Mount Wilson Observatory, also in California. Astronomers now eagerly searched old plates of spirals for further novae. By late 1917 sufficient numbers of novae had been located for Curtis to dismiss the 1885 nova in the Andromeda nebula as abnormally bright, and thus not a reliable indicator of the nebula's distance. Curtis now compared the brightness of the typical novae in spirals with the average brightness of novae within the Galaxy, and in so doing he estimated these spirals to be a hundred times more distant than the galactic novae, thereby, in the opinion of Curtis and other astronomers, providing yet more evidence for the island universe theory. Indeed, by the end of 1917 nearly all of the leading students of spiral nebulae judged it likely that they were external galaxies.

A key issue here is that the Galaxy was also the measuring rod against which supposed galaxies were measured, and contemporary estimates of the dimensions of the Galaxy played a part in determining the status of the island universe theory. This point became particularly important when in late 1917 HARLOW SHAPLEY conceived and fashioned a bold new model of the Galaxy in which its diameter is roughly 300 000 ly—roughly 10 times larger than the commonly accepted estimates—and in which the Sun is placed some tens of thousands of light-years from its center. Certainly Shapley came to be loathe to accept that the spirals were comparable with his gigantic stellar system and he suggested that they were truly nebulae, but he wavered on the status of the spirals and between 1917 and 1920 he changed his mind three times on their relation to the Galaxy. Shapley's writings on the spirals did nevertheless bring him an invitation to participate in what has become one of the best-known, but often misunderstood, events in 20th century astronomy: the so-called 'Great Debate'.

The 'Great Debate' and internal motions

In April 1920 Shapley and Curtis both delivered talks on 'The scale of the universe' to the National Academy of Sciences, one of America's most prestigious scientific bodies.

Shapley chose to speak at a very popular level (most likely his chief concern at the Debate was to appeal to the members of the audience concerned with selecting the next director of the Harvard College Observatory, a job Shapley coveted), and it was only after the Debate, with the published papers of Shapley and Curtis, that the protagonists actually came to grips with each other's arguments. In his published paper Curtis maintained that the spirals were external galaxies, arguing chiefly on the basis of the by now familiar observations of their spectra, radial velocities and novae. Curtis also attacked Shapley's estimate of the size of the Galaxy. Curtis and many others had advocated a comparable-galaxy theory (that is, a theory in which the spirals were not just external galaxies, but in addition were comparable in size with the Galaxy). He admitted that if the spirals were as large as Shapley insisted the Galactic system to be, then the spirals would be at such enormous distances that the novae within them would have to be impossibly bright, thereby undermining the case for the comparable–galaxy theory.

During the late 1910s and early 1920s another class of observations came to play a leading role in the island universe debate: the measurements of the internal motions of the spirals. ADRIAAN VAN MAANEN (1884–1946), a Mount Wilson astronomer, began his investigations of this topic in 1915 when he scrutinized photographic plates, taken some years apart, of the giant spiral M101 (that is, number 101 in Charles Messier's catalog of nebulae). His goal was to detect and measure the size of any changes in appearance in the intervening years, and he decided that M101 did indeed exhibit a rotation, or, more likely in his view, motions along its spiral arms. At first the internal motions did not obviously conflict with the island universe theory. The English applied mathematician and theoretical astronomer J H JEANS (1877–1946) in fact exploited van Maanen's measures to champion the island universe theory and to buttress his own theories on the origin and development of spiral nebulae. Jeans' theories were very influential, especially among the Mount Wilson astronomers, and they were brought before a wide audience in his *Problems of Cosmogony and Stellar Dynamics* of 1919.

In his 'Great Debate' paper Shapley wrote little on external galaxies and largely confined himself to arguing that their fate was inextricably bound to his theory of the Galaxy. However, Shapley did cite the measurements of the internal motions of spirals made by van Maanen, claiming that these could not fit into a scheme in which the spirals were galaxies 300 000 ly in diameter—the size he claimed for our own Galaxy—as the sizes of the internal motions then implied velocities for the outlying regions greater than the velocity of light. This was, he judged, a clear reduction to absurdity of the island universe theory.

In the early 1920s van Maanen measured several more spirals and found that his results agreed very well with his earlier ones for M101. Some astronomers harbored doubts about the internal motions nevertheless. The motions were almost the only evidence against the island universe theory of spirals; and if the spirals were not galaxies, what were they? In particular, how could one interpret the spectrum, radial velocity and nova observations? These considerations persuaded some astronomers that

van Maanen's scrutinies had not revealed real motions. Thus while the island universe theory lost some support, many judged it to be, on the whole, still much the best available explanation of the properties of spiral nebulae.

Hubble and Cepheids

The sudden, and unexpected, resolution of the debate on the existence of external galaxies was effected in late 1923 and 1924 by a series of discoveries made by the Mount Wilson astronomer EDWIN P HUBBLE (1889–1953).

Hubble had completed his doctoral dissertation on 'Photographic investigations of faint nebulae' in 1917 at a time when the island universe theory was very much in fashion and he seems to have been inclined towards it from this date on. After a brief period in the US army, he joined the Mount Wilson staff in 1919. In 1923, he decided to obtain plates of the Andromeda nebula in the hope of recording novae flaring in the nebula. For someone anxious to establish an accurate distance to the nebula this program had much to recommend it. In particular, by observing more novae he would be able to determine with greater precision the mean apparent brightness of novae in the nebula and thus estimate their distance—and so the nebula's—with more certainty than had been the case. He was also excellently placed to pursue such a program because he had access to the world's most powerful telescope, the Mount Wilson 100 in, and the rich resources of the world's leading astrophysical observatory.

He indeed found novae in the nebula, but in early 1924, to his surprise, he also decided that a star he had earlier identified as a nova was in fact a Cepheid variable. Hubble constructed a light curve for the Cepheid variable and rapidly secured its period. Then by assuming (as Shapley had done earlier in his studies of the Galaxy) that Cepheids of the same period have the same intrinsic luminosity wherever they are found, Hubble had been able to exploit the Cepheid period–luminosity relationship to calculate the nebula's distance. His result of 900 000 ly placed it far beyond the boundaries of even Shapley's model of the Galaxy. Astronomers also quickly agreed that Hubble had resolved the outer parts of the nebula into swarms of stars. Moreover, he soon found more Cepheids in the Andromeda nebula and some other spirals that supported his early findings. The Cepheids were accepted by the opponents of the island universe theory to be accurate distance indicators to the spirals, and the Cepheids' unambiguous message was that the spirals were indeed external galaxies, a message confirmed by almost all of the other evidence. The only discrepancy came with the internal motions, but soon nearly everyone rejected them as hopeless exaggerations of any real motions, and the case for their accuracy had collapsed under the weight of opposing evidence. Within a year or two of Hubble chancing upon the first Cepheid, the debate on the existence of island universes had effectively ended.

Once Hubble had settled the question of galaxies, astronomers began to turn increasingly to other problems associated with the spirals. One was how to classify

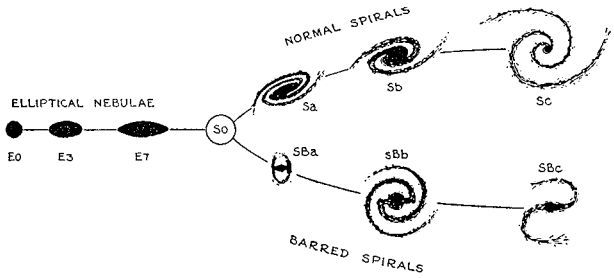

Figure 1. Hubble's 1936 sequence of nebular types.

them. In the 1910s Curtis had divided the nebulae into three main groups: diffuse nebulae, planetary nebulae and spirals. While Curtis's decision to create one grouping of 'spirals' had drawn attention to them as possible external galaxies, by the mid-1920s this scheme seemed to some astronomers to be far too restrictive and alternative classifications were advanced. The most influential was Hubble's, first proposed in 1922 and later elaborated by him (figure 1). Although Hubble claimed that the scheme was purely descriptive and independent of any theory, he was an enthusiastic advocate of Jeans's theories on the origin and development of extragalactic nebulae and this revealed itself clearly in his scheme. By 1926 Jeans had rejected van Maanen's measures as worthless, but in Hubble he had found another champion of his own theories. Hubble agreed with Jeans that there was one basic type of extragalactic nebula and that the various stages of development of this one type could explain the appearance of nearly all the observed extragalactic nebulae. Jeans placed the elliptical nebulae, which he believed to be enormous galaxy-sized clouds of dust and gas, at the beginning of the evolutionary sequence of these nebulae. He argued that the end of the elliptical stage is marked by the build up of spiral arms from the material of the nuclear regions. As this process continues, the nebula increases in size, until the arms are wide open and the nucleus inconspicuous. As a spiral ages its arms start to break up into condensations. These are proto-stars or proto-star clusters, and, as the spiral develops, the region of star formation moves inexorably inwards.

The Jeans theory of nebular evolution was rejected by, among others, Shapley and the Swedish student of nebulae, Knut Lundmark (1889–1958), who asserted that even elliptical nebulae were star systems, and who both emphasized the importance of possible gravitational interactions with other galaxies for the evolution of an individual galaxy. For this reason Hubble always used the term 'extragalactic nebulae' while Shapley employed 'galaxies', and these terms became shibboleths dividing East and West coast astronomers in the United States (indeed it was not until after Hubble's death in 1953 that 'galaxies' was universally adopted). Shapley and Lundmark both proposed hypotheses in which the Galaxy is composed of a number of smaller, interacting galaxies. They had done so in part because, despite the uncertainty

about the size of the Galaxy, by 1930 it seemed likely to the majority of astronomers that it was far larger than any other known star system.

The expansion of the universe

Shortly after he had turned seriously to the classification of nebulae, Hubble began to tackle another outstanding and perplexing problem in extragalactic research: whether or not there is a relationship between the distance of a galaxy and the size of its REDSHIFT.

V M Slipher, as we saw earlier, was the first to measure the radial velocity of a spiral nebula, and by 1914 he had been able to announce the radial velocities of 15 spirals. To secure these exceptionally faint and elusive spectra he required lengthy exposure times, sometimes as long as 80 h. Slipher's progress was therefore slow, and others were usually content to leave these difficult and tedious labors to him. However, as Slipher doggedly measured more velocities, a curious pattern began to emerge: nearly all of them were shifts to the red end of the spectrum; that is, if the spectral shifts were interpreted as Doppler shifts, all but a few were velocities of recession. In addition, the radial velocities were generally very much larger than those of the stars or gaseous nebulae, and their very sizes prompted some to query the Doppler, or velocity, interpretation of the spectral shifts.

Meanwhile, another development suggested that the radial velocities might be correlated with such distance-related variables as the diameters of the spirals. This possibility arose largely through a hypothesis advanced by the Dutch astronomer Willem de Sitter. In 1917 de Sitter had discovered an alternative solution to that found by ALBERT EINSTEIN (1879–1955) to the field equations of the general theory of relativity. de Sitter's solution, moreover, predicted a relationship between redshift and distance for distant stars and galaxies. As astronomers usually understood it, this relationship was not just the result of a recession of far-off bodies. Rather, the intrinsic properties of space and time in de Sitter's solution cause clocks to run more slowly the further they are from the observer. Hence, the atomic vibrations within a distant galaxy appear to slow down, the frequency of light decreases, the wavelength increases and a redshift is observed. de Sitter's solution applies strictly to an empty universe, but de Sitter himself and a number of his contemporaries thought that, if the density of matter was sufficiently low, it might be applicable to the real universe.

Even before the significance of de Sitter's model had been realized, there were speculations about a redshift–distance relation. However, as general relativity became more widely discussed and the notion became established of developing theoretical models of the entire universe that could be compared with actual observations, so de Sitter's model of the universe gained in plausibility, and in the 1920s it became generally agreed that, if de Sitter's model approximated the actual properties of the universe, then a relationship between redshift and distance was to be expected. Although there was much debate over the exact form of the relationship, it became widely accepted that, the greater the distance of a body, the larger should be its redshift.

Early attempts by C A Wirtz, Lundmark and others to establish a relation failed to gain support principally because the distances to the spirals were not known accurately, and these pioneers had been compelled to employ, for want of anything better, the very crude and, to other astronomers, unconvincing distance indicators of constant absolute magnitudes and constant absolute diameters.

Hubble, however, with the aid of the Mount Wilson 100 in reflector, was far better equipped than his competitors to investigate the redshifts and distances of extragalactic nebulae. He was also able to call on MILTON HUMASON (1891–1972), an outstanding observer, to make the demanding and time-consuming measurements of the redshifts.

To determine the distances of galaxies, Hubble exploited a carefully constructed distance 'ladder' that used a series of interlocking distance indicators, the most important rung of which was the Cepheid period–luminosity relationship. By applying this ladder Hubble obtained the distances to 24 of the 46 extragalactic nebulae whose redshifts had been determined, almost all by Slipher. The other 22 nebulae were not used in his primary proof because he reckoned they were not in groups and average apparent magnitudes could not be taken. When Hubble plotted the redshifts of the 24 nebulae against their distances he judged that a linear redshift–distance relation was the simplest way of representing his data, indicating a systematic recession of the nebulae represented by $V = kr$ (in which the k term is today known as Hubble's constant H, V is the velocity and r the distance). Furthermore, when distances were calculated (by means of apparent magnitudes) to the remaining 22 nebulae whose redshifts had been measured, they too, in Hubble's judgement, fitted the linear relation well.

By 1929 such a relation was not unexpected; indeed, in 1930 Hubble himself told de Sitter that 'the possibility of a velocity–distance relation among nebulae has been in the air for years—you, I believe, were the first to mention it'. The attempts of Wirtz, Lundmark and others to determine observationally the nature of the relation had failed to win general acceptance, but they had undoubtedly helped to prepare the way for Hubble's researches. Hubble had worked within a well-defined problem area, using a well-defined method, and had expressed his argument with care, stressing the solid observational basis of the relation, particularly the reliability of his distance measurements. His achievement was to persuade his colleagues that there was indeed a linear relation, at least to a first approximation.

The linear relation was swiftly incorporated into theoretical models of the universe. By early 1930 mathematical cosmologists had become acutely aware of the inadequacies of the static solutions of the field equations of general relativity as representations of the

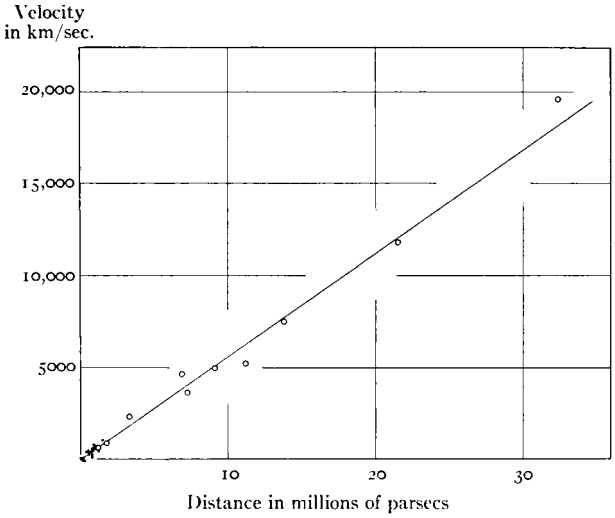

Figure 2. Hubble and Humason's 1931 apparent velocity–distance diagram. The dark circles in the bottom left hand of the plot represent the data from Hubble's 1929 paper on 'A relation between distance and radial velocity among extra-galactic nebulae'.

universe, but at this point a paper by the Belgian cosmologist GEORGES LEMAÎTRE (1894–1966), ignored when first published in 1927, was 'rediscovered' and was now welcomed enthusiastically. The combination of Lemaitre's theorizing and Hubble's handling of the observations convinced many that the static solutions had failed because the universe is in fact expanding, and the redshift–distance relation a natural consequence of this expansion. Expanding models, widely neglected during the 1920s, were now eagerly explored and after 1930 accorded a central role in extragalactic astronomy and cosmology. Indeed, by this time a research enterprise had come into being that centered on the nature and evolution, as well as the relationships between different sorts, of galaxies and their place in an expanding universe.

Hubble, however, preferred not to identify the redshifts definitely as Doppler shifts. Also, he regarded his 1929 paper as a preliminary report and not the publication of a completed piece of research. He particularly wanted to test the linear relation against more distant nebulae, and in 1931 he and Humason announced their latest findings (figure 2). Now he calculated that the most remote extragalactic nebula lay at an estimated distance of 32×10^6 pc, a large increase when compared with the furthest at 2×10^6 pc in the 1929 plot. There were, moreover, many more points on the 1931 diagram because 40 more redshifts were available, and Hubble judged the linear relation to be much clearer than in 1929. This rapid extension had been made possible by the combination of an extremely efficient spectrographic objective on the 100 in Mount Wilson telescope—at this time still the most powerful in the world—and Humason's skill as an observer. In the 1931 paper Hubble also sought to distinguish carefully between observation and interpretation. He emphasized that Humason had measured redshifts, and that they were not necessarily Doppler shifts. Although, as we have noted, many astronomers and mathematicians believed that the redshift–distance relation signified an expansion of the universe, others were incredulous at the size of the 'velocities' Humason was finding: if the redshift of one nebula was a genuine radial velocity, then it was receding at a staggering 19 700 km s^{-1}. Furthermore, if one simply extrapolated the present expansion back in time with no allowance for a possible acceleration in the expansion, the redshift–distance relation implied that there was a time about 2×10^9 yr ago when all the material in the universe had been packed together. For the numerous astronomers who accepted Jeans's estimate of 10^{13} yr as the age of the Galaxy, this time was far too recent, especially as the time scale for stellar evolution was also expected to be of this order. How, they asked, could the age of the Galaxy and its stars be much greater than the age of the universe? In consequence, the time scale problem spawned several (but by general agreement unconvincing) attempts to invent an alternative mechanism to the Doppler effect that would explain the redshifts.

While the debate on the nature of the redshifts has still not been finally settled, by the early 1950s the time scale problem had dissolved: astronomers had concluded that revisions of the cosmic distance scale meant that the present expansion rate did not conflict with estimates of the ages of the stars and galaxies. There were two main reasons for this change of opinion. First, astronomers now concluded that Hubble had mistaken H II regions—clouds of ionized gas—for the brightest stars in extragalactic nebulae. Since these clouds are intrinsically more luminous than stars, it meant that the corresponding distances had been underestimated. Secondly, the period–luminosity relationship for the Cepheids had been dramatically revised by WALTER BAADE (1893–1960).

Baade, a German-born astronomer, had joined the Mt Wilson staff in 1931. However, when the US entered World War II he was counted as an enemy alien. He did, nevertheless, receive special permission to use the Mt Wilson telescopes, and, with the aid of red-sensitive photographic plates and the war-time black-out of Los Angeles (the city was already a significant source of light pollution for the observatory), Baade managed to resolve into stars the central regions of the Andromeda nebula. Baade went on to argue that there are two distinct types of stars in spiral galaxies, population I (young blue stars found in dusty regions) and population II (old red stars found in dust-free regions). He later decided that there are two different period–luminosity relationships and the determining factor deciding which of the two a Cepheid belonged to was its population type. A major consequence of Baade's findings was that the distances established by means of Cepheids of population I had to be increased by a factor of 2, one consequence of which was that astronomers decided to double the galactic distance scale.

Clusters

Until 1926 the studies of the arrangement of the nebulae had been largely restricted to their distribution on the sky, but in that year Hubble made the study three dimensional when he examined the frequency distribution of diameters and apparent magnitudes (both being approximate indicators of distance) of some 400 extragalactic nebulae. He found that the numbers of nebulae to different limits (roughly, distance limits) were proportional to the volumes of space represented by the limits. Thus he argued there is an approximately uniform density of nebulae in all directions (with the exception of the Galaxy and the Virgo cluster of galaxies), given the assumption that the relative number of giant, normal and dwarf galaxies was the same in each of his samples. During the 1930s Hubble made further extensive studies of the space density of extragalactic nebulae as a function of the distance from our Galaxy. His method was to count extragalactic nebulae to various limiting magnitudes over widely spread areas of sky. Such counts confirmed his belief that, although nebulae are found singly, in groups and even occasionally in great clusters, when very large regions of space are compared the tendency to cluster averages out and one region is very much like any other.

Shapley, however, argued that Hubble was mistaken. In 1932, he published the Shapley–Ames catalog of galaxies, which, he reckoned, was complete to magnitude 12.9. To him, the catalog revealed a general lumpiness of distribution, with galaxies tending to form clusters and lumps, the most notable of which was the Virgo cluster. Shapley later extended the limits of his surveys to the 18th magnitude; again he reckoned clustering was a prominent feature. Indeed, by the early 1950s, clustering had become widely accepted as a major characteristic of the large-scale distribution of galaxies, and Hubble's hypothesis of a general field occasionally disrupted by groups or clusters of galaxies had fallen from favor. In 1952, G de Vaucoleurs, using the Shapley–Ames catalog and elaborating on a number of earlier speculations, also argued for the existence of clusters of clusters, or superclusters, to explain the distribution of bright galaxies on the sky.

Concluding remarks

At the start of the 20th century astronomers had believed that our Galaxy constituted the entire visible universe, but within 30 yr it had become accepted that space contains a multitude of visible galaxies. These galaxies, moreover, were found to display a redshift–distance relation, a relation that was generally taken to indicate that the universe is expanding. These triumphs convinced astronomers that future progress in cosmology would probably be dependent on the construction of ever more powerful optical telescopes. The giant 200 in reflector at Mount Palomar, completed in 1948, was in part a product of this belief. The redshift–distance relation and the models of an expanding universe had indeed produced an exchange between theory and data in studies of the large-scale properties of the universe that had been undreamt of in the early years of the century. Yet it was to be the unexpected extension of observations beyond the narrow range of optical wavelengths, to radio waves with wavelengths greater than 10 m and γ waves with wavelengths shorter than 10^{-12} m, that was to do most to fashion the next stage in the development of extragalactic astronomy.

Extragalactic Background Light

Extragalactic background light (EBL) is the integrated flux from all extragalactic sources, including those which are not individually detected. In keeping with the COSMOLOGICAL PRINCIPLE—that the universe should appear homogeneous and isotropic to a typical observer—the EBL is expected to have a uniform mean level on large angular scales over the sky.

The cosmological significance of the EBL was first recognized as early as the 1700s, when astronomers imagined the universe to be a static volume of space, uniformly filled with stars. In this cosmological picture, the number of stars at a distance, r, increases as r^2, canceling the $1/r^2$ fall-off in the apparent brightness of a single star and making the total flux from objects populating every shell of space a constant value. This view led HEINRICH WILHELM OLBERS and others to conclude that the nighttime sky should be as bright as the daytime sky. The dilemma presented by the fact that the sky is (relatively) dark at night became known as OLBERS' PARADOX. This apparent conflict is now easily explained by the expansion of the universe, the finite speed of light and, most importantly, the finite lifetimes of stars. However, Olbers' paradox stands as an excellent illustration of the power of background measurements to test our model of the universe.

Ironically, while the night sky is far from dark, extragalactic sources contribute less than 1% of the sky brightness from the ultraviolet (UV) to the infrared (IR). Terrestrial, zodiacal and Galactic sources produce foreground emission which dominates the sky flux, making the diffuse EBL very difficult to measure, but also causing strong bias against the individual detection of faint or low surface brightness galaxies and intergalactic stars. Measurements of the diffuse EBL are immune to surface brightness selection effects. The EBL therefore provides a complete census of the energy density in the universe, making it a very powerful constraint on models of STAR FORMATION and the baryonic content of the universe.

Sources of the EBL

The majority of the EBL at UV to IR wavelengths is produced by stars at all REDSHIFTS since the first stars formed. In the far-UV (∼1000–1600 Å), Lyman continuum absorption by hydrogen in the intergalactic medium limits the objects contributing to the EBL to those at redshifts below $z \sim 1600$ Å/912 Å $- 1 \sim 0.8$. In addition, the UV light from galaxies is produced by the hot, massive stars, which are also responsible for most of the nuclear processing of hydrogen into helium and heavier elements (generally called 'metals'). The far-UV EBL thus traces the global star formation and metal production rate in the last half of a Hubble time.

The sources of the EBL become more complicated at optical (3000 Å–1 μm) and IR (1–1000 μm) wavelengths because the light we detect in those bands originates from objects over a wider range of redshifts and, consequently, emitted wavelengths. The optical EBL includes the direct emission from STELLAR POPULATIONS out to redshifts of $z \sim 10$. The energy density from stellar populations peaks at 1–1.5 μm at most stellar ages, so that the optical EBL will include both older populations at low redshift and young populations at high redshift.

Finally, much of the stellar emission in the universe will be contribute to the far-IR background, both because the light from the earliest generations of stars (most distant stars) will be redshifted to longer wavelengths and because UV–optical photons will be absorbed by dust grains in the emitting galaxy and re-radiated as thermal emission at infrared wavelengths ($\lambda \gtrsim 10$ μm). Dust attenuation of short-wavelength light is very efficient and may prevent more than 30% of the star formation in the universe from being directly detected at wavelengths shorter than 1 μm.

Non-stellar emission, such as the gravitational potential energy from accreting black holes and emission from decaying particles, will also contribute to the EBL. It is also possible that a significant fraction of the baryons in the universe might reside in a primordial INTERGALACTIC MEDIUM of ionized gas which might be identified by its contribution to the EBL. While hot gas at a temperature of $T \sim 10^6$ K would emit x-rays, and cool gas ($T \sim 10^4$ K) would produce dramatic absorption features in quasar spectra, gas at a temperature of $T \sim 10^5$ K would be detectable only by its contribution to the EBL through redshifted He II emission at 304 Å and Lyα at 1216 Å.

Measuring the EBL

Figure 1 shows the surface brightnesses of the foreground sources as a function of wavelength along lines of sight where these sources are faintest—at Galactic latitudes greater than 65° and ecliptic latitudes greater than 30°. For comparison, EBL detections and upper limits are shown in figure 2, along with models of the expected EBL and lower limits derived by summing the flux from resolved extragalactic sources (i.e. detected galaxies) and models of the EBL. At all wavelengths, the cumulative flux from foreground sources is roughly 100 times that of the EBL.

Ultraviolet (1000–2500 Å)

Because the atmosphere is opaque to photons with wavelengths shorter than about 3100 Å, UV observations must be made from rockets or from space. Early efforts to detect the far-UV background were inspired by the fact that the only bright foreground source documented at the time—ZODIACAL LIGHT—drops off sharply below 4000 Å and becomes insignificant below 2000 Å. However, the measurement was more difficult than expected and results varied by 3 orders of magnitude. With hindsight, it is clear that poor spatial resolution made subtraction of Galactic stars extremely difficult in these experiments and that the instrumental backgrounds were poorly understood. In addition, line emission from atoms and simple molecules (H I, O, and NO) at altitudes above 300 km and solar Lyα photons contributed significant flux to the rocket-based measurements.

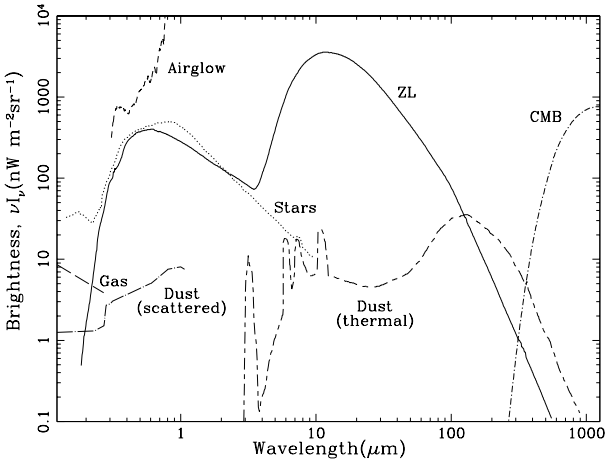

Figure 1. The flux from foreground sources is shown for lines of sight at Galactic latitudes greater than 65° and ecliptic latitudes greater than 30°, where foregrounds are faintest. The curve marked by short dashes at 0.3–1 μm shows the airglow contribution to ground-based observations: below 0.3 μm, the atmosphere is opaque; above 1 μm, the atmosphere is too bright for background observations. The solid curve shows zodiacal light, with the scattered component peaking around 0.6 μm and the thermal component peaking around 10 μm. The short-long dashed curve shows thermal emission from interstellar (Galactic) dust, with strong emission features around 3, 6, 8 and 10 μm. Scattered light at UV to optical wavelengths from the same dust is marked by a dot–dashed curve. The long dashed curve shows the Galactic UV contribution composed of atomic and molecular line emission and continuum emission from interstellar gas (see text). The dotted curve shows the flux from discrete Galactic stars fainter than $V = 6.0$ mag. The dot–short dashed curve shows the cosmic microwave background radiation (2.73 K).

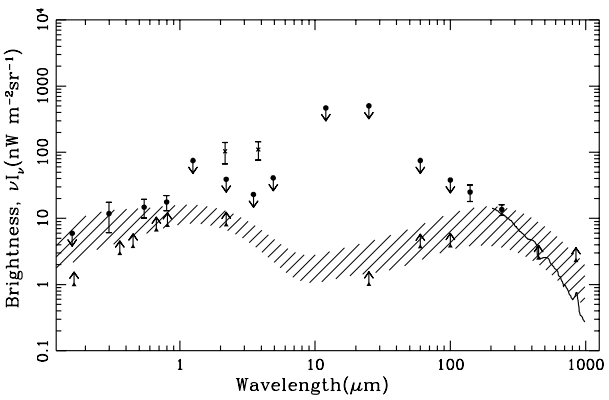

Figure 2. Measurements of the surface brightness of the EBL from the UV to the IR are indicated by filled dots and by the dark, solid curve. Upper limits are indicated with downward arrows. Upward arrows indicate lower limits to the EBL from the integrated flux of detected sources (galaxy counts). The hatch-marked region shows the range predicted by various models based on UV–optical source detections when dust obscuration is included (see Dwek *et al* (1998) for details).

Rapid progress came around 1980, with the advent of UV detectors with better resolution and greater sensitivity. Results in the last few decades have consistently shown that the majority of the UV background originates within the Galaxy, with only a small component being isotropic and therefore possibly extragalactic. The majority of the Galactic contribution is diffuse, dust-scattered starlight. The scattered flux can be estimated based on the intensity of the thermal emission from the same dust, which identifies the column density of dust, and simple scattering models incorporating empirically and theoretically determined dust properties. The previously poor agreement between modeling efforts now seems well explained by evidence that interstellar dust is strongly forward scattering. The scattered UV flux therefore depends on the scattering angle between the line of sight and the incident starlight from the center and plane of the Galaxy. Line emission from [O III] 5007 Å, C IV 1550 Å and O III] 1663 Å has also been detected in correlation with the column density of neutral hydrogen, as have H_2 fluorescence (1550–1650 Å), two-photon, bound–free and free–free continuum emission, and Lyα (1216 Å) and Hα line emission, all from warm ($T \sim 10^5$ K), high-latitude gas. The intensity of these components is proportional to the cosecant of the Galactic latitude, which approximates the path length through smoothly distributed gas.

Measurements and limits in the last 10 yr have converged towards EBL fluxes in the range 2–5 nW m^{-2} sr^{-1}, with a minimum estimate of 1 nW m^{-2} sr^{-1} from the cumulative flux in detected sources. Emission from galaxies is apparently responsible for the majority of this flux, while quasars and active galactic nuclei are estimated to contribute less than 0.2 nW m^{-2} sr^{-1} and flux from any intergalactic medium is limited to less than 0.2 nW m^{-2} sr^{-1} between 912 and 1216 Å.

Optical (3000 Å–1 μm)

The Earth's own atmosphere was the greatest impediment to early efforts at measuring the optical EBL. Atmospheric emission (AIRGLOW) is not only at least 100 times brighter than the EBL but also can vary by several per cent on timescales of minutes, as can atmospheric extinction. These effects make it nearly impossible to correct for atmospheric emission and extinction to the required accuracy. The only demonstratedly successful method for dealing with the atmosphere is to avoid it by conducting measurements of the EBL from space. The dominant foreground source contributing from beyond Earth's atmosphere is sunlight scattering off of the large ($\geq$10 μm), rough, INTERPLANETARY DUST grains which concentrate in the ecliptic plane. This scattered zodiacal light is also at least 100 times brighter than the flux of the EBL, even at ecliptic latitudes of $|b| > 35°$. As the solar system is harder to escape than the Earth's atmosphere, it is fortunate that the scattering involved is well described by Mie scattering theory and is only weakly wavelength dependent, with scattering becoming more efficient by ~5% per 1000 Å toward longer wavelengths. The mean zodiacal light flux

can therefore be measured using the strength of solar absorption features (FRAUNHOFER LINES) which are preserved in its spectrum.

Optical CCD detectors typically have subarcsecond resolution, which makes resolution and subtraction of stars in our own Galaxy relatively easy. However, as in the UV, interstellar dust scatters incident starlight, producing diffuse Galactic light at optical wavelengths. Thermal emission from dust and the correlation of dust with neutral hydrogen can both be used to identify the lines of sight with the lowest dust column density, and simple scattering models can be used to estimate and subtract the low-level contribution which remains. The scattering properties of the dust are inferred from observations of the diffuse Galactic light at near-UV wavelengths where it dominates the sky and also from observations of a few neutral hydrogen (H I) clouds and planetary nebulae, where dust column densities are high.

Ground-based efforts to measure the optical EBL started in the 1970s. Airglow was identified either by geometrical modeling or by beam switching between a clear line of sight and a 'dark' dust cloud at high Galactic latitude in order to isolate the foreground from background sources. In 1980, the *Pioneer 10 Explorer* obtained data not only from above the atmosphere but from beyond the zodiacal dust cloud at a distance of 3 AU from the Sun. While it avoided both airglow and zodiacal light, the *Explorer*'s poor resolution made the subtraction of even discrete Galactic sources (i.e. stars) very difficult. As in the UV, rapid progress has been made with the advent of high-resolution detectors above the atmosphere aboard the *Hubble Space Telescope*. Detections of the EBL at 3000, 5500 and 8000 Å have recently been reported based on coordinated HST imaging (see HUBBLE DEEP FIELDS) and ground-based spectroscopy.

Infrared (1 μm–1000 μm)

Any warm body emits thermal radiation, including telescopes, the Earth's atmosphere and the Earth itself. Observations of the IR EBL must therefore be made from space with cryogenically cooled detectors. From space, thermal emission comes from dust trapped in the solar system and in the Galaxy. Subtraction of these foregrounds depends on spectral modeling using multiwavelength observations and geometrical modeling based on all-sky coverage. The most ambitious and successful IR measurement to date was undertaken with the *Cosmic Background Explorer* (*COBE*), launched in 1989. Prior to *COBE*, progress was made using short-lived, rocket-borne telescopes and satellites intended for observations of discrete sources, such as the *Infrared Astronomical Satellite* (*IRAS*).

Zodiacal light from scattering dies off at a wavelength of a few microns, but thermal re-emission of absorbed sunlight from the same dust peaks around 10 μm. This thermal emission is recognizable from the motion of the Earth in its orbit through the zodiacal dust. The annual variation of the sky brightness in all directions can be modeled empirically and subtracted. Once the thermal zodiacal component is removed, some individual Galactic sources can be resolved and subtracted. Flux from unresolved, discrete Galactic sources can be determined at each wavelength based on detailed statistical models of galactic sources and their spatial distribution. The diffuse emission from interstellar dust is brightest at around 100 μm. This component can be estimated and subtracted at wavelengths longer than 100 μm by scaling the zodiacal light-subtracted, 100 μm observations using a temperature model of the dust.

The *COBE* observations produced 3σ detections at 140 and 240 μm and 2σ upper limits at 100 μm and shorter.

Testing the big picture

The difference between the cumulative flux in optically detected sources and the detected optical EBL indicates that roughly 50% of the flux from individual sources is beyond the spectroscopic detection limit of current redshift surveys (see figure 2 and also GALAXY REDSHIFT SURVEYS). Recent results show that the difference may be partially explained by low surface brightness objects which are not included in standard catalogs and missed flux in low surface brightness regions of the objects which are catalogued. At longer wavelengths, however, the individual sources which produce the IR EBL have not been completely identified and may be powered by stellar or non-stellar sources. More generally, upper limits, lower limits and detections of the EBL all seem to indicate that the energy density in extragalactic sources is roughly constant over 4 orders of magnitude in wavelength (0.1–1000 μm). This spectral shape alone is a very interesting constraint on our models of the universe. The mean EBL at any wavelength is a complicated function of emission rates from stars, dust extinction, evolution of galaxies and the initial mass function and evolution of the stellar populations themselves. Meaningful interpretation of the EBL therefore requires modeling these variables as a function of redshift. Such models—which characterize our picture of the universe—are constructed from observations of resolved sources as a function of redshift.

One method for modeling the EBL is based on measurements of the rest-frame UV emission of individual galaxies, which indicates the star formation rate as a function of redshift and subsequently the EBL as a function of wavelength. Uncertainties in the dust attenuation of UV and optical light in the emitting galaxies limit the accuracy of these models. Other uncertainties include the stellar initial mass function and spectral energy distributions, which together identify the number of stars forming with a given mass and the spectral output from those stars. Models of the EBL based on this method need to include significant ($\gtrsim$30%) dust obscuration and re-radiation in order to provide reasonable agreement with observations of the infrared EBL. This necessity indicates that star formation regions at all redshifts are largely dust enshrouded and optically dark.

The conversion rate of neutral hydrogen gas into stars as a function of redshift can be inferred from the statistics of absorption features in quasar spectra. This provides another method of modeling the EBL. As with the models based on UV rest-frame emission, the dominant uncertainty in these models is the fraction of optical light attenuated by dust and the characteristic temperature of the dust. As metals are produced through NUCLEOSYNTHESIS in the same hot, young stars whose output dominates the EBL, the mean EBL also can be predicted by the total metal mass density in the local universe. CLUSTERS OF GALAXIES are a convenient place to measure metal density, because any metals which may be ejected from galaxies will be trapped in the cluster potential. The rate of metal production can also be traced by absorption features caused by intervening systems in quasar spectra as a function of redshift. The total metal enrichment in the universe as identified by either method agrees with the total EBL energy density detected to date to within a factor of 2–5.

After more than 25 yr of work in the field, measurements or well-quantified upper limits have been found for the EBL over the full wavelength range from the UV to the IR. To within the measurement and modeling uncertainties, the results at all wavelengths produce a generally self-consistent picture of the total star formation rate in the universe, the total metals produced in stars and the total energy output from nucleosynthesis. Additionally, at wavelengths shorter than 1 μm, the diffuse background can be accounted for by sources which are well understood and largely present in surveys of individually detected galaxies. Efforts to better quantify the EBL UV and mid-IR wavelengths are underway in the form of new satellite missions and programs to identify the sources of the IR background.

Extragalactic Reference Frames

The conceptual basis of reference frames defined by extragalactic objects is straightforward: that the universe as a whole does not rotate so very distant objects cannot have an overall rotational motion. Experimentally, the global rotation of the universe is less than 10^{-12} arcsec yr^{-1} as inferred from the 3 K microwave background radiation. At the distance of 10^8 parsec, even if an object were moving transversely at the speed of light, its angular velocity would be less than 0.6×10^{-3} arcsec yr^{-1}, while an object moving at a physically more reasonable speed comparable to the Sun would show a motion of 10^{-6} arcsec yr^{-1}, entirely undetectable by current technology. Since neither systematic universal motion nor random motion at such great distance is measurable, it is reasonable to construct a static celestial reference frame on the basis that such objects are fixed in the sky.

The idea of using extragalactic objects to define the celestial reference frame is quite old, having been discussed by Herschel and Laplace some 200 years ago, even before there was proof that such objects existed. The discovery of external galaxies and their distances in the early twentieth century raised the possibility of their use as fiducial objects for the celestial reference frame. However, their fuzzy, faint optical images made it quite difficult, and ASTROMETRY continued to use bright stars despite the complications of significant random and systematic motions. Fortunately, observations in the radio frequencies in the 1960s revealed a class of objects that has proven to be suitable for astrometry of the highest order, albeit with some limitations. These are QUASARS, compact radio sources which are pointlike in the optical band but with large REDSHIFTS implying cosmological distances.

Very long baseline interferometry

The technique for measuring the positions of quasars and similar objects is VLBI (very long baseline interferometry). In this application, VLBI is a geometric technique that measures directions in space with great accuracy. Schematically, using a pair of distant antennas, the difference in the time of arrival at the two stations of signals emitted by a radio source is measured with a precision of a few picoseconds. For a typical baseline of 5000 km, this corresponds to a fraction of a milliarcsecond. This time difference (delay) and its first derivative (delay rate) are reconstructed by offline correlation of the signals (actually radio noise usually buried in the thermal noise of the electronics) recorded at the two ends of the baseline. A key piece of equipment at the stations is the clock used to time events. VLBI makes use of hydrogen masers with stability of one part in 10^{14} for both time and frequency, and the raw data are recorded digitally at rates up to 1 Gbit s^{-1}. In current practice a network of up to 20 stations observes 50–80 radio sources around the sky multiple times during a 24 h session. Since a delay and a delay rate are generated from each pair of stations for each time a source is observed, there can be upwards of 20 000 delay/delay rate data points from one observing session. VLBI observations suitable for high-precision astrometry began in the late 1970s with the development of dual-frequency receivers and the Mark III VLBI data acquisition system, and an active worldwide observing program continues.

The analysis of VLBI data for astrometric and geodetic purposes requires the estimation of source positions, station positions, nutation corrections and parameters characterizing the behavior of the clock and atmosphere at each station as well as careful modeling of all geophysical and astronomical effects. Each separate session provides the relative positions of the observed sources with some uncertainty. On different days different sets of sources are observed. It is the overlap of some common sources from one day to another that connects all the positions together. From all the overlaps and directly measured positions come the complete set of relative positions. Repeated measurements, either directly in one day or indirectly from different days, improve the precision of the inferred positions. Having varied combinations of baselines and sets of observed sources strengthens the overall geometry and weakens the correlations between the source coordinates and the numerous phenomena modeled in the analysis. In particular, a mixture of north–south and east–west baselines is needed to determine both components of source position. Since VLBI measurements give relative positions, the orientation of the ensemble of positions, i.e. the pole and right ascension origin, must be determined from external information. This is a necessary step in assigning the numerical position values that define the reference frame. In practice the intermediate results are manipulated as the usual right ascension and declination values, but the fundamental VLBI measurements are of the arclengths between sources, the precision of which is contained in the full covariance matrix of the set of source positions. The earliest VLBI positions in 1971 were no better than a few arcseconds, but by the mid 1980s a few milliarcseconds had been achieved.

Unlike stellar astrometry, which must rely on a conventional theory of PRECESSION and NUTATION to transform true date coordinates to mean coordinates of the standard epoch, VLBI astrometry is sensitive to the errors in the standard precession/nutation model, which amount to several milliarcseconds. To achieve the full accuracy inherent in the stability of extragalactic positions, it is necessary to allow for corrections to the precession/nutation theory. This can be accomplished in two ways, either by adjusting the precession constant and various nutation coefficients or by estimating the offset between the actual pole and the modeled pole for each day of observation.

Foundation of the extragalactic reference frame

The process of laying the conceptual foundation for the extragalactic reference frame, identifying its fiducial objects and developing the fundamental catalog was begun at the Twentieth IAU General Assembly in Baltimore in 1988 by a

resolution stating 'The International Astronomical Union should adopt a celestial reference frame based upon a consistent set of coordinates for a sufficient number of extragalactic objects when the required observational data have been successfully obtained and appropriately analyzed. ... This reference frame is likely to be based, initially at least, exclusively upon radio astrometry.' The Working Group on Reference Systems headed by J Hughes was established with subgroups for time (B Guinot), coordinate frames and origins (J Kovalevsky), astronomical constants (T Fukushima), and the theory of nutation (D McCarthy). The fundamental concepts (see also SPACE AND TIME REFERENCES: CONCEPTS) of what is now the ICRF (International Celestial Reference Frame) were developed by the subgroups and extensively discussed at the IAU Colloquium 127 on Reference Systems held in Virginia Beach in 1990. The general theory of relativity for space and time, the use of extragalactic radio objects, and the continuity between the existing stellar and the anticipated extragalactic celestial reference frames were summarized in nine recommendations adopted as a resolution by the Twenty-first IAU General Assembly in Buenos Aires in 1991. A working group under C de Vegt was formed to select the radio sources to be used with emphasis on the need to connect the radio and optical frames. The Twenty-second IAU General Assembly in The Hague in 1994 adopted the list of some 600 sources and established a new working group under L Morrison to define the positions. This work was done by a subgroup of VLBI and celestial reference system specialists. The resulting ICRF catalog was adopted by the Twenty-third IAU General Assembly in Kyoto in 1997 and came into effect on 1 January 1998, replacing the FK5. A Working Group for the International Celestial Reference System (ICRS) under F Mignard was formed to carry on the ICRF work, to extend the frame to other objects and frequencies, and to elucidate the consequences of the ICRF.

Definition of the ICRF extragalactic reference frame

According to the new adopted rules, the fundamental directions of the celestial reference system will remain fixed in space; they will no longer be dependent on modeling the motion of solar system objects. The fiducial objects will be monitored. The adopted positions may be revised when improved information is available, but the coordinate axes will be maintained by implementing the statistical condition that the coordinates of selected defining sources show no global rotation from the old set of coordinates to the new realization.

The data used to determine the ICRF radio source positions included 1.6 million pairs of dual-frequency delays and rates from 1979 to the middle of 1995. The data were contributed from several geodetic and astrometric observing programs, the vast majority of the observations coming from the former but most of the sources coming from the latter. The design of the analysis was intended to provide (1995) state of the art source positions, in particular to free the results from contamination from precession/nutation errors, anomalous source behavior, geodetic noise and systematic atmospheric effects. Simultaneous dual-frequency observations provided the calibration of ionospheric dispersion. Celestial pole offsets in obliquity and longitude were estimated for each day. Positions of sources with excessive scatter or apparent motion (as determined from test solutions) were estimated separately for each day as were station positions. An elevation limit of 6° was adopted to balance the need for maximum observing geometry against the difficulty in correctly modeling the atmosphere at low elevations. Atmospheric gradients were estimated to remove a significant systematic effect. Both delays and rates were used to maximize the information available and to decrease correlations.

Because of the large number and high quality of observations, the formal errors for the positions were exceedingly small and not a meaningful measure of uncertainty. It was necessary to consider several other effects to assign realistic errors. One was the statistical validity of the formal errors. Another was the cumulative influence of all modeling errors and editing decisions. Yet another was the magnitude of specific, identifiable errors that could have distorted the results. A consideration of all known error sources indicated that a realistic error estimate could be made by inflating the formal errors by a factor of 1.5 followed by a root-sum-square increase of 0.25 milliarcsecond. For the most frequently observed sources 0.25 milliarcsecond was the dominant error.

The sources from the ICRF solution were divided after the fact into three categories: 212 defining sources that met a series of quality criteria; 294 candidate sources that failed one or more of the quality criteria, e.g. too few observations or observing interval too short, and 102 'other' sources (whose positions were estimated each day). While the distribution over the sky of the ICRF as a whole is quite uniform, the defining sources are sparser in the southern hemisphere because of a dearth of VLBI stations and limited observing programs. The 'other' sources include a number with relatively bright optical counterparts that could be used to connect the radio and stellar frames.

The axes of the frame were aligned to the International Earth Rotation Service (IERS) realization of the ICRS with an error of $\sim$0.020 milliarcsecond. The Hipparcos catalog, which is the optical realization of the celestial reference frame (see HIPPARCOS AND TYCHO CATALOGUES), was aligned to the ICRF, largely through VLBI observations of radio stars. The ICRF also provides the framework for various space geodetic techniques to measure the terrestrial positions and velocities that constitute the terrestrial reference frame and to monitor variations in the rotation of the Earth.

Future improvements

The two chief phenomena leading to random and systematic errors in the ICRF are the atmosphere and source structure. While the propagation delay at zenith from the dry atmosphere can be accurately calibrated from

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

local meteorological data, the dry delay in the line of sight to the observed source is subject to modeling error. The delay from water vapor cannot be calibrated accurately, and both delays are subject to random temporal and spatial fluctuations that must be estimated from the VLBI or other microwave data.

Quasars are not point radiators. Source structure can cause their position to appear slightly different depending on baseline geometry, and changes in source structure can cause apparent movement. Detailed source maps show that intrinsic variations in structure can be quite extreme, ranging from relatively compact naked-core objects, to compact double sources, to complex core-jet objects. The situation is complicated by the fact that compact extragalactic RADIO SOURCES are known to have variable intensity and to have frequency- and time-dependent intrinsic structure. Consequently, unknown and unmodeled source structure effects may be introduced into the reference frame. The sources can be characterized after mapping by the degree to which the delay and delay rate are affected by the structure over the full range of possible baseline geometries, and the worst sources can be rejected for most astrometric purposes.

As of the beginning of 1999, about 800 000 more observations including about 50 new sources had been acquired by geodetic and astrometric programs since the ICRF was constructed in 1995. These were integrated with the data and analysis used for the ICRF to update the original catalog. The original ICRF analysis was not copied exactly to incorporate new data, but the new positions are consistent with the ICRF at its stated level of accuracy, about 0.25 milliarcsecond in overall source positions and about 0.020 milliarcsecond in orientation. Positions were determined for new sources, and updated positions and errors were found for candidate sources with additional observations. The positions and uncertainties of the defining sources were not changed since they are the actual realization of the ICRF, and the work to include more recent data does not lead directly to the replacement of the existing ICRF. The defining sources will be used in a no-net-rotation condition relative to the ICRF to ensure that positions from new analyses are aligned with the ICRF.

There are several features that distinguish the ICRF from conventional stellar catalogs that formerly defined the celestial reference frame. First, the quasars are optically faint so connection to the stellar frame is complicated. Second, while the positional history of the radio sources is known, the results of future observations cannot be predicted. Consequently, new sources must be observed to replenish and expand the list of candidates. Third, as new observations accumulate, it should be possible to move candidate sources up or down the scale of usefulness in subsequent ICRF realizations. The problem of position changes related to source structure variation may be solved in the future if the application of source structure information permits the identification and use of truly kinematically static points in the sky. Since the original VLBI delay and delay rates are accessible, they can always be reused in improved analysis. When models and estimation techniques are significantly improved and sufficient data are accumulated, a new ICRF can be constructed *de novo*.

Extrasolar Planetary Companions and Brown Dwarfs

The first convincing detection of both extrasolar planets (EXOPLANETS) and brown dwarfs came during the 1990s[1]. The first planetary system found around another star is actually a very special case: the host is a 6.2 ms pulsar, a billion year old NEUTRON STAR which should formerly have erupted as a supernova. From precise timing of the radio pulses, A Wolszcan and D A Frail determined the orbits of three inferred terrestrial-mass companions in 1992. The leading model for the formation of pulsar planets involves post-supernova capture of a small amount of material from a preexisting companion into an ACCRETION DISK. The apparent existence of planets in such an exotic environment may tend to indicate that planet formation can take place under a wide variety of conditions, but we do not consider this case further here.

The inferred existence of the first Jovian-mass extrasolar planet in a normal stellar environment was found by detection of periodic radial velocity variations in the optical spectrum of the Sun-like G star 51 Peg; the discovery of 51 Peg B was announced in 1995 by M Mayor and D Queloz of the University of Geneva. Over the next few years several groups utilized this the Doppler technique to report dozens of discoveries.

In the same few-month period of 1995, the first bona fide brown dwarf—instantly recognizable as a substellar object—was reported by a group of Johns Hopkins University and California Institute of Technology scientists (see bibliography). In contrast to the first case, the latter was a direct detection of the brown dwarf as a resolved, distant companion to the nearby M dwarf Gliese 229. Since this object, called GL 229B, features methane (CH_4) rather than carbon monoxide (CO) in its infrared spectrum, its surface temperature was inferred to be near 1000 K—much too cool to be a star. Methane is also the dominant form of carbon in the atmosphere of Jupiter. In figure 1 we display a recently published infrared spectrum of GL 229B with the methane and water bands labelled. For comparison are shown spectra at similar wavelengths of the late M dwarf vB10 and the L dwarf GD 165B (see the final section). These considerably warmer objects show H_2O and CO, but not CH_4.

In retrospect, as will be discussed, GL 229B may not have been the first brown dwarf to be discovered. Several different techniques have yielded candidate substellar-mass objects over the last 10 yr. In the next section we summarize the techniques that have been tried or are planned for the future. Then we summarize briefly some findings and their implications as of early 1999. In figure 2, kindly made available by Dr Alan Boss, the distribution of most known extrasolar planets and brown dwarfs as of early 1999 is shown as a plot of mass (in M_J) versus orbital semimajor axis (in AU). Other features of this plot will be discussed subsequently.

Direct detection techniques

The direct detection of GL 229B was made possible by its photospheric radiation. In a later section the discoveries of more luminous brown dwarf candidates in both young star clusters and the field will be discussed. It is obviously a much more difficult task to detect directly a cold planet. In the visible the reflected light from a Jupiter analog is typically $\sim 10^{-9}$ that of the primary star. In the thermal infrared (5 μm and greater), this contrast may be as small as 10^{-4} for an old planet. Direct imaging of a planetary or cold brown dwarf companion requires that the noise in the point spread function of the primary's light profile be reduced accordingly. As of this writing, only a few brown dwarf companions (and no planets) have been detected directly in this way. For the future, ADAPTIVE OPTICS systems with a coronographic capability are being developed for the new generation of 8–10 m telescopes.

For example, in 2001, The ADONIS (Adaptive Optics Near Infrared System) instrument mounted at the European Southern Observatory (ESO) 3.6 m telescope at the La Silla Observatory has obtained an image of a dust disk around the star iota Horologii, already known to possess a planet at least twice as heavy as Jupiter in an Earth-like orbit. The dust disk around iota Horologii is quite extended; it is detected to a distance of about 65 AU (10 000 million km) from the star. From the elongation, it appears that the inclination of the disk is about 42º.

Also promising for direct detection of planets is ground-based interferometric imaging in the infrared (see also INTERFEROMETRY: GROUND). Direct imaging of Earth-like planets will require development of a space-borne interferometer with a baseline of ~100 m and perhaps 4 m apertures.

Astrometric detection

The astrometric signature of an orbiting planet is a periodic wobble proportional to both the planet's mass and its orbital radius (see ASTROMETRY: TELESCOPES AND

[1] For this discussion, a brown dwarf is defined as a configuration incapable of sustained hydrogen fusion reactions, with a mass between about $0.01M_\odot$ and the stellar mass limit of $(0.075–0.08)M_\odot$. These values correspond very nearly to 10 and 75–80 Jupiter masses (M_J), respectively. A giant planet is defined as having a mass less than about $10M_J$ and thus is incapable of even limited nuclear burning of deuterium. In addition, theoretical calculations tend to favor a lower mass limit for formation of isolated entities (brown dwarfs) of the order $10M_J$. An upper limit to the mass of a Jovian planet can be inferred from the limited amount of gas in a circumstellar disk and its finite lifetime; this has been suggested to be not more than several Jovian masses.

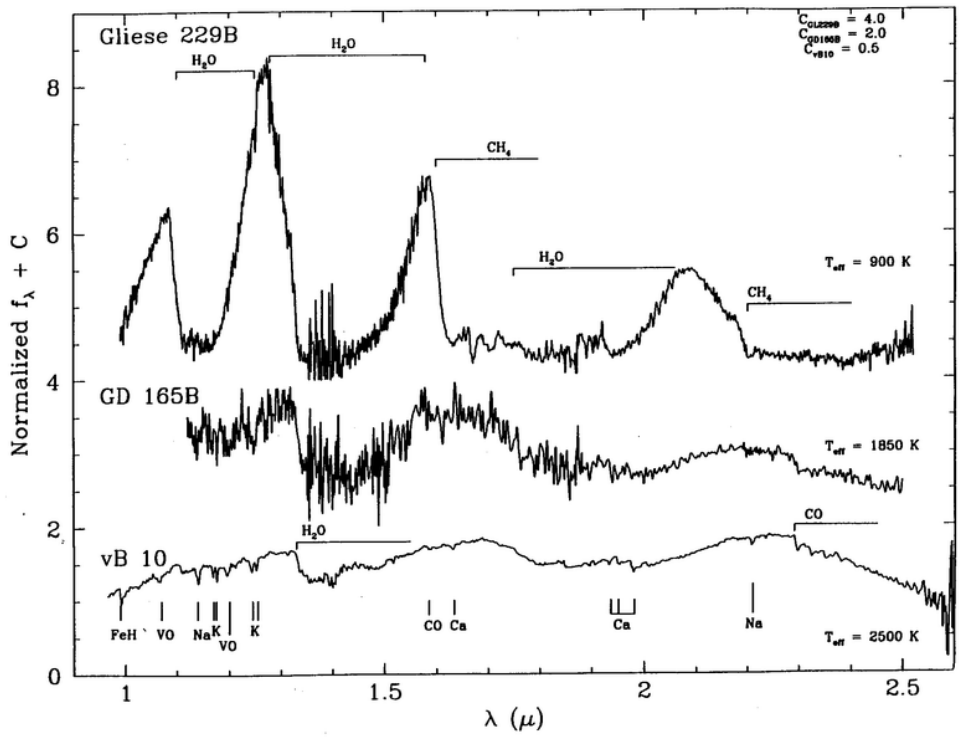

Figure 1. The near-IR spectrum of GL 229B compared with spectra of vB10 (M8 V) and GD 165B (L2 V, see the last section of this article). The great strengths of the CH_4 and H_2O bands in GL 229B give it a blue J–K color. From Oppenheimer B R, Kulkarni S R, Matthews K and van Kerkwijk M H 1998 *Astrophys. J.* **502** 932.

TECHNIQUES). It is therefore nicely complementary to the Doppler radial velocity technique which is biased in favor of nearby companions; this technique is also insensitive to the viewed orbital inclination. A Jupiter at 4 AU from a solar-type star 10 pc away would produce an astrometric amplitude of only 0.5 milliarcsec (mas). The sensitivity of an astrometric measurement to 1 mas is shown as the long–short dashed diagonal line in figure 2, from top left to bottom right. Objects falling to the right of the line are detectable by this method, if the orbital periods are not prohibitively long. Jupiter by itself would be a marginal detection in a solar system clone. In the future as astrometric precision is refined from milliarcseconds down to microarcseconds (from space), this technique can become very powerful. The reality of the astrometric companion alleged for Lalande 21185 (figure 2) is now questionable. To date no definitive detection of a planetary companion has been accomplished by astrometry.

Photometric detection

Several ground and space programs and proposals are underway which will attempt to detect planets and brown dwarfs undergoing transits of a parent star. The Jovian planet will dim a G star primary by the order of 1% (the ratio of surface areas), a terrestrial planet by only 0.01%. Another photometric signature to be exploited is gravitational MICROLENSING. With suitably high time-resolution sampling, the microlensing surveys can reveal the photometric signatures of foreground substellar objects in the light of background stars such as those observed in the crowded fields of the GALACTIC BULGE.

Detection by periodic radial velocity variations

As discussed in the introduction, it is the Doppler technique which has yielded bountiful discoveries of extrasolar planets in several years of work. The general expression for the semiamplitude, K, of the stellar radial velocity induced by an orbiting companion is

$$K = \frac{2\pi G}{P^{1/3}} \frac{m_{\rm p} \sin i}{(M_* + m_{\rm p})^{2/3}} \frac{1}{(1-e^2)^{1/2}}.$$

Newton's refinement of Kepler's third law then yields $m_{\rm p} \sin i$ and the orbital radius a (see KEPLER'S LAWS)[2].

[2] Originally, it was also proposed that some mechanism other than orbital motion was responsible for the apparent periodic Doppler signature. However, subsequent research has shown that orbital motion is the only plausible interpretation, despite the unexpectedly short orbital periods implied for some of the planetary companions.

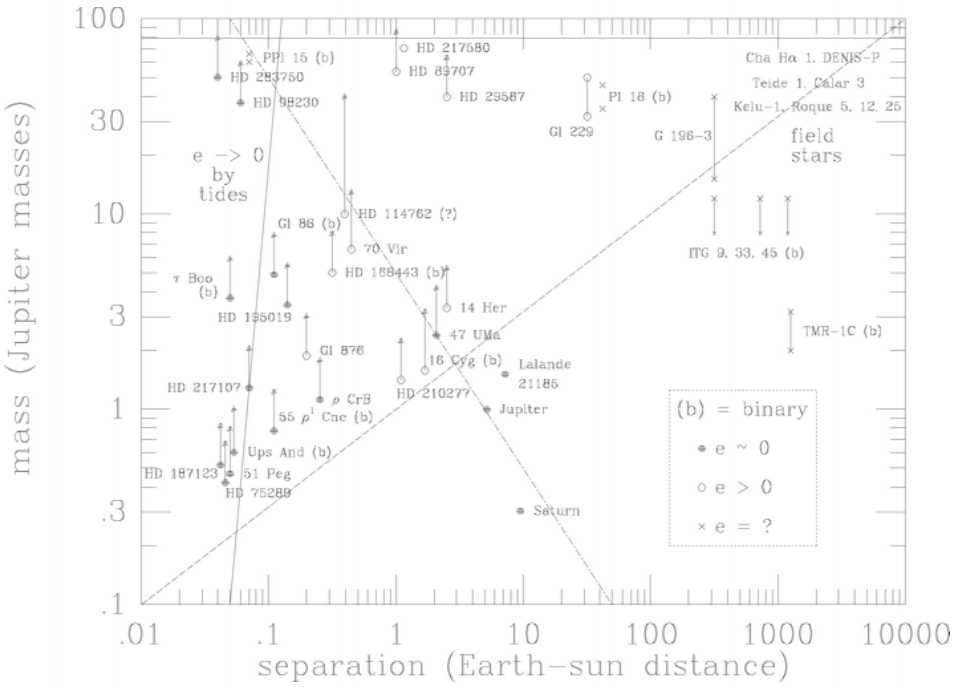

Figure 2. Extrasolar planets and brown dwarfs known as of early 1999, masses (M_J) versus separation (in AU). Arrows indicate that most mass estimates determined from the Doppler technique are lower limits. Filled, open circles and ×s indicate circular, eccentric and unknown eccentricity orbits. Jupiter and Saturn are also plotted. Some field brown dwarfs are plotted arbitrarily in the upper right with rough mass estimates. To the left of the solid line orbits should be circularized owing to tides (51 Peg B objects). The dashed line gives sensitivity for Doppler amplitude of 30 m s^{-1}. The nearly perpendicular long–short dash line gives complementary sensitivity for an astrometric wobble of 1 mas.

The high accuracies to which K is now measured are due to the development of precise spectrographs designed for this purpose (see SPECTROGRAPHS: HIGH-RESOLUTION SPECTROGRAPHS). The Sun orbits the barycenter of the solar system with a typical velocity of only 13 m s^{-1}. A few groups have achieved measurement errors as low as 3 m s^{-1}, accurate enough to detect the effects of Jupiter and Saturn at least marginally if they were to observe a solar system clone. Their various techniques involve superposing the wavelength calibration scale directly on the stellar spectrum, to remove even small effects of spectrograph flexure when the telescope moves. The accuracy of the Doppler technique in ferreting out periodic radial velocity variations in the spectra of solar-type stars is limited directly by the 'noise' due to motions in the stellar atmospheres. The dispersion of velocity measurements increases linearly with the stellar rotational velocity, which is known to correlate with general stellar activity. An active star may even display a Doppler-like velocity signature at the stellar rotation period.

The dashed line approximately perpendicular to the astrometric line in figure 2 maps the sensitivity of a radial velocity amplitude of 30 m s^{-1}; this shows the complementary nature of these techniques. Since virtually all extrasolar planet discoveries were made using the Doppler technique, the known cases fall above and to the left of this line. The arrows indicate that the mass determinations are always lower limits, since the orbital inclination is generally unknown. Thus many possible brown dwarfs in the upper left may in reality be low-mass stars, the result of selection bias. In fact the evidence currently is that there are few brown dwarf companions found close to stars in the solar neighborhood. Some objects in the upper right include single brown dwarf candidates to be discussed later.

Properties of extrasolar planets

The preceding discussion indicates that the current list of known objects is biased by the selection constraints of the Doppler and astrometric methods. In particular the sensitivities to Jovian planets at the separations observed for those in our solar system are marginal, and the time baselines are still too short for even one orbital period to be fully sampled. That Jovian planets may be found inside of 1 AU separation is now obvious, and these of course are found most easily. Two distinct groups deserve special discussion.

One group including the first object 51 Peg B lie in circular orbits of less than 0.1 AU separation. Objects falling to the left of the solid curve near 0.1 AU in figure 2 lie so close to the parent star that the orbits must be circularized, as is observed to be the case.

Theoretical work on Jovian planet formation argues strongly that they could not accrete and grow to Jovian mass in the hot inner region of the circumstellar nebula. It is believed that they must have migrated inwards before the gaseous phase of the disk ended, since the dissipation of the orbital angular momentum depends on the presence of viscous gas. It is possible that some Jovian planets accrete onto the host star and may even enhance the surface abundance of some elements.

A second peculiar group are the Jovian planets and possible brown dwarf companions in eccentric orbits. These lie to the right of the tidal circularization line, as they should. A planet with the most elongated orbit detected so far (September 2001) is HD 80606, which moves between 5 and 127 million km from the central star. Since the standard model of accretion in a gaseous disk to form a massive planet should circularize its orbit, it is likely that a dynamical interaction of two of these bodies occurred. It is also possible for a planet to be ejected from the system.

The upsilon Andromedae solar system includes both types: there is a close $>0.7M_J$ planet of period 4.6 days in a circular orbit, a $>2M_J$ planet with a 241 day period in a mildly eccentric orbit and a $>4.6M_J$ planet in an eccentric orbit with a 3.5 yr period. In summary, the distribution of objects plotted in figure 2 is certainly biased heavily, but the discoveries nonetheless demonstrate how versatile the formation of solar systems can be.

Brown dwarfs in young clusters and star-forming regions

Young, nearby clusters have offered the opportunity to detect brown dwarfs when they are relatively luminous and at a predicted luminosity and age. Primarily on the basis of ground-based surveys at wavelengths of 0.8–2 μm, dozens of brown dwarf candidates have been found in photometric surveys of several young CLUSTERS such as the Pleiades and star-forming regions in Orion and rho Ophiuchus. The systemic membership of the candidates may be confirmed by astrometric and radial velocity measurements, as well as the fact that the candidates fall on a sequence in a color–magnitude diagram predicted by models of gravitationally contracting, protostellar objects. In 2001, observations by the European Southern Observatory's New Technology Telescope revealed dusty disks surrounding brown dwarfs in the Orion Nebula, suggesting that they are more star-like than planet-like and have the potential to form accompanying planetary systems. This finding is based on detailed observations with SOFI, a specialized infrared-sensitive instrument at the European Southern Observatory's (ESO) 3.5 m New Technology Telescope (NTT) at the La Silla Observatory.

The detection of lithium is another important constraint on the existence of objects below the stellar mass limit. In particular, lithium is believed to undergo destructive fusion reactions at an interior temperature ($\sim(2–3)\times10^6$ K) slightly below the limit for proton–proton fusion. Fortunately, calculations of the interior structures of very-low-mass stars and brown dwarfs predict that energy is transported primarily by convective motions from the centers to the very surfaces. This means that, if lithium is hot enough to be depleted at the center where the temperature is highest, it will eventually be depleted throughout the configuration. Therefore, if the resonance lines of Li are observed in stellar atmospheres (at the strength expected for the abundance at which the gaseous body should have formed), hydrogen is also not being fused in the deep interior—i.e. the configuration is a brown dwarf. Numerous such detections of the Li lines have been reported, and an Li luminosity boundary consistent with theory has been found in the Pleiades. This 'lithium test' thus enhances the likelihood that Pleiades substellar candidates Teide 1, Calar 3 and the Roque objects (figure 2, upper right) are part of the substellar extension of the Pleiades mass function as low as $30M_J$.

Brown dwarfs in the local Galactic disk

Follow-up observations of 'field' point sources detected in the near-infrared sky surveys DENIS (Deep Near Infrared Survey) and 2MASS (Two Micron All Sky Survey) have shown that brown dwarfs exist in the field as single objects. 2MASS in particular has discovered ~100 brown dwarf candidates (as of this writing). While warmer than GL 229B, these infrared-selected objects are cooler than the M dwarf stars, with $T_{\rm eff} < 2000$ K.

In 2001, two examples have been discovered of small, cool stars that resemble brown dwarfs but are actually the remnants of ordinary stars that have been whittled down to cool Jupiter-sized bodies over billions of years by spilling material over to a white dwarf companion star. Using the UK Infrared Telescope (UKIRT) in Hawaii, the first direct evidence of such stars was obtained by taking infrared spectra with the CGS4 instrument of two variable binary star systems: LL Andromedae and EF Eridani. The observers took advantage of periods when the flow of material between the two stars in these binary systems temporarily stops. At these quiescent times, UKIRT can distinguish the radiation coming from the cool donor star. In the case of LL Andromedae, the signature of methane was detected at a wavelength of 2.2 microns. This shows that the donor star's temperature is around 1300 K, similar to a 'T-type' methane brown dwarf. In EF Eridani, the donor star is a little warmer, at around 1650 K, similar to an'L-type' brown dwarf. According to theory, the estimated mass of these cool stars is near four-hundredths the mass of the Sun, or 40 times the mass of the planet Jupiter, with estimated distances of between 100 and 130 light years.

An assessment of a complete subsample of 2MASS L dwarfs suggests that substellar objects are comparable with or outnumber the stars in the solar neighborhood, though contributing only modestly to the mass of the local disk (see GALACTIC THIN DISK). It appears that only young brown dwarfs—or those relatively few likely to have masses just below the stellar mass limit—are observed in the L dwarf temperature range and are readily detectable by 2MASS and DENIS. This implies that the great majority have cooled to much lower temperatures. Indeed, field objects showing methane in the spectra and with temperatures closer to that of GL 229B (~1000 K) have now also been found, by the Sloan Digital Sky Survey (SDSS) and by 2MASS. It may well turn out that the majority of the Sun's substellar neighbors have cooled to temperatures of several hundred kelvin, cooler even than GL 229B.

Breaking news update (31 January 2002)

Observations by NASA's Hubble Space Telescope of the gas-giant planet orbiting the yellow, Sun-like star HD209458, 150 l.y. from Earth have revealed the presence of sodium in light filtered through the planet's atmosphere when it passed in front of its star as seen from Earth. The planet was discovered in 1999 by its subtle gravitational pull on the star. The planet is 70% the mass of Jupiter. Its orbit is tilted nearly edge-on to Earth, which allows repeated transit observations. The planet is only about 6 million km (4 million mi) from the star. At this distance the planet's atmosphere is heated to around 1000 K.

At the time of this update 66 extrasolar planetary systems are confirmed, consisting of 74 planets and 7 multiple planets systems. See http://www.obspm.fr/encycl/catalog.html. Among recent discoveries are three Jupiter-sized planets travelling in circular orbits similar to that of Earth and Mars in our own solar system.

Extrasolar Planets

The discovery of the first planets around a PULSAR (1992) and around a main sequence star different from our Sun (1995) has opened, after centuries of speculation, a new era in astronomy. The motivations for the search for 'other worlds' are presented. A comparative review is given of different techniques for their detection. Special attention is paid to the planetary parameters which can be derived in each method. The first discoveries and their astrophysical consequences are presented. A review of new questions and future projects beyond these first discoveries is given.

Introduction

The search for 'other worlds' is one of the oldest well-formulated scientific questions. It was raised for the first time in 'modern' terms by the Greeks (Democritus, Epicurus). Since then, it has inspired many thinkers (Giordano Bruno, Fontenelle, Goethe, Kant, …), but it was pure speculation. There had been a first attempt in the 17th century by HUYGENS (1698), who tried to see planets around other stars. He quickly realized that this observation was far beyond the capabilities of his modest telescope. After that, for centuries, seeing such planets could only be a dream. A new hope appeared in the early 20th century after the astrometric and spectroscopic detection (explained further in this article) of 'unseen' companions to stars (i.e. very faint stars). However, the expected planetary masses were to small to be reached by these methods. Astronomers had to become patient again. A slim hope was raised by the Dutch astronomer P VAN DE KAMP in the 1950s: he thought that he had detected a planet around BARNARD'S STAR (one of our closest stellar neighbors), but it was later proven to be an artefact. The first important step was made by Frail and Wolszczan when they detected the first planets around a pulsar. It was a great encouragement for planet hunters, although the star itself (a neutron star) was too odd to resemble our Sun. The good news was heard in October 1995, when the Swiss astronomers Mayor and Queloz claimed the detection, thanks to the RADIAL VELOCITY method using a telescope at the Haute Provence Observatory (south of France), of a planet around the star 51 Peg, similar to the Sun. Understandably enough, there was some skepticism after decades of mistakes, but only for a few weeks. This great discovery makes us live in a very special epoch, where progress on the 23-century-old question 'Are we alone in the universe?' has made a major step and the question can be investigated scientifically.

This first discovery was followed by many others; since then, more and more planets have been discovered (by radial velocity measurements of the parent star) each year and there are at present (September 2001) 66 of them (see also EXTRASOLAR PLANETARY COMPANIONS AND BROWN DWARFS). Table 1 gives the current list (updated frequently on the internet (Schneider 1999)). Furthermore, for one of the stars (upsilon Andromedae), three planets have been detected. For another star, one could measure the radius of the planet (30% larger than Jupiter); this observation is a definite proof that the stellar wobble is indeed due to a giant, gaseous, planet.
In 2001, a two-planet system was detected (around the star HD 82943) in which one orbital period is nearly exactly twice as long as the other. HD 74156 is another two-planet system with a Jupiter-like planet and a more massive planet farther out. A giant planet moving in an orbit around a Sun-like central star (HD 168443) already known to possess a planet has been detected, as well as a planet with the most elongated orbit detected so far (HD 80606), moving between 5 and 127 million kilometers from the central star.

In one of the systems, 55 Cnc, a dust disk has been found around the star, first as an IR excess by ISO (Dominik *et al* 1998), and subsequently as an image at the IRTF (Trilling and Brown 1998). The inclination of the disk as deduced from the image shape is ~25°.

After this turning point it is possible to go further, and astronomers are now willing to address several questions.

1. How frequent are other planetary systems?
2. Are they like ours (number, masses, radii, albedos of the planets; radii, eccentricities, inclinations of their orbits)?
3. What types of environments (atmospheres, magnetospheres, rings etc) do they have and what are their properties?
4. What are the other physical properties of planets (rotation period, atmospheric circulation, presence of oceans, …)?
5. How do they form and evolve?
6. How do these features vary with the type of the central star (mass, spectral type, chemical composition, age, binarity etc)?

In addition to these purely astrophysical questions, there is a related query, shared by every human: 'is there life elsewhere in the universe?' This question raises the problem of the different forms of life we can expect outside the solar system and the problem of the definition of life. The convential view is that life can develop on Earth-like planets in the 'habitable zone' (where the temperature is about 300 K) around stars. Beyond the detection of these planets, it is even possible to search for spectroscopic signatures of life on these 'habitats'.

The detection methods for extrasolar planets

To investigate these planetary systems, astronomers use several methods of detection and observation.

Extrasolar planets can be detected by either direct or indirect methods. Each detection method is characterized by some observables which are related to the instrinsic physical parameters of the planet. These parameters are their mass M_P, radius R_P, temperature T_P, distance a from the parent star, orbital period P, brightness L_P and distance D from the solar system. The potential success of a given method depends naturally on its instrumental limitations.

Direct imaging

The most natural gesture to detect a planet is trying to 'see' it. However, planets have generally no intrinsic emission, at least in the optical wavelength range. One

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

can only detect their illumination by the parent star. However, one then faces a severe problem: the light reflected by the planet is extremely faint and, at the same time, the planet is extremely close to its star, so that it is very difficult to separate them. Indeed, for a planet orbiting at a distance a from a star with a brightness L_*, the stellar light is dispersed over the whole area $4\pi a^2$ of the sphere of radius a on which the planet is located. The planet receives only a small fraction of this light, proportional to the surface πR_P^2 of the planetary disk seen by the observer. The planet thus acquires by reflection a brightness L_P given by

$$L_P = L_* \frac{\text{planetary disk area}}{\text{area of the sphere at the planet's distance}} = \frac{L_*}{4}\frac{R_P^2}{a^2}.$$

Because the planetary radius is much smaller than its distance to the star, the brightness ratio L_P/L_* is very small: it is 2.5×10^{-9} for a Jupiter.

On the other hand, the planet is seen by the observer at an angular distance $\alpha = a/D$ from the star, i.e. very close to it (fractions of arcseconds). The planet, in addition to being very faint, is then embedded in the light halo of the star owing to the telescope's diffraction. The addition of the planet's faintness and its closeness to the star makes its detection very difficult. To circumvent this difficulty, several tricks have been invented: 'nulling imaging', 'dark speckle imaging', 'phase mask coronography', 'hyper-telescope', …. All of them are intended to extinguish the star as much as possible (without extinguishing the planet). They use the wavelike properties of light by making the star interfere destructively with itself, without affecting the nearby planet. For observations from the ground, there is an additional source of degradation of images: the atmospheric turbulence. One can, in that case, increase the sharpness of images by 'adaptive optics', a technique which counterbalances the deformation of images by the atmosphere by deforming slightly, in real time, the telescope mirror (see INSTRUMENTATION: ADAPTIVE OPTICS).

The ADONIS (Adaptive Optics Near Infrared System) instrument mounted at the European Southern Observatory (ESO) 3.6 m telescope at the La Silla Observatory has obtained an image of a dust disk around the star iota Horologii, already known to possess a planet at least twice as heavy as Jupiter in an Earth-like orbit. The dust disc around iota Horologii is quite extended; it is detected to a distance of about 65 AU (10 000 million km) from the star. From the elongation, it appears that the inclination of the disk is about 42º.

Despite the difficulties presented by this direct detection, astronomers put much effort into it because it is the only way to access several properties of the planet. As an example, the careful study of the time evolution of the planet's reflection, in different colors, can reveal its diurnal rotation period, its seasonal variation, the relative amount of water at the surface (oceans) etc.

Dynamical perturbation of the star by the planet

Instead of seeing the planet directly, one can search for its effects on the parent star. The first of these effects is the gravitational perturbation of the star's position by the planet. When the planet makes a revolution around its parent star, in fact both objects are in orbit around their common center of mass. Thus the star makes a small circular orbit with a radius $a_* = aM_P/M_*$ and a period naturally equal to the planetary orbital period P (see figure 1 by G Marry).

For the observer, this small orbit results in perturbations of three of the star's observables: its radial velocity V_R (the velocity in the direction of the star's line of sight), its position α on the sky with respect to a fixed star and the time of arrival of signals regularly emitted by the star. These three observables are perturbed with a period equal to the planet's orbital period and with an amplitude proportional to the planet's mass. The measurement of this amplitude therefore gives a determination of the planet's mass. In fact, for radial velocity measurement and time-of-arrival measurements a slight complication arises: if the inclination of the planetary orbit is not known, the method gives only a minimum value of the mass. The best example of regularly spaced signals is the periodic emission of pulsars. The first planets (in fact three and perhaps four) were discovered by this method by Wolzsczan and Frail around the pulsar PSR 1257+12. The amplitude of the radial velocity variation is 13 m s^{-1} for a Jupiter at 5 AU from its parent star. Figure 2 shows the periodic variation of the radial velocity of the star 51 Peg as a function of time ($\phi = 1$ corresponds to $t = 4.23$ days) measured by Mayor and Queloz. It was the first planet ever detected around a Sun-like star. After this first discovery, an interesting new step was the detection, by the same method, of three planets around the star upsilon Andromedae.

The precision in radial velocity measurements is at present 3 m s^{-1}. Thus it becomes possible to detect Saturns by radial velocity measurements. However, there is no hope of detecting an Earth since the radial velocity perturbation produced by such a planet is only 10 cm s^{-1}.

Planetary transits

The planet can produce a drop in the star's light during transits of the star's disk by the planet. The detection of a TRANSIT in the star's lightcurve requires two conditions to be satisfied.

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

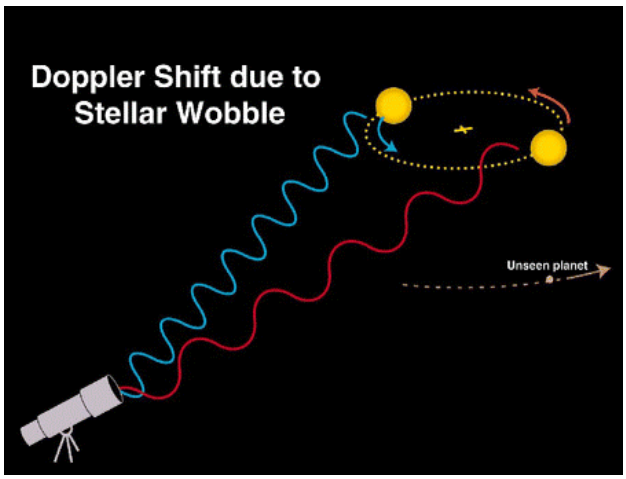

Figure 1. Doppler shift due to stellar wobble.

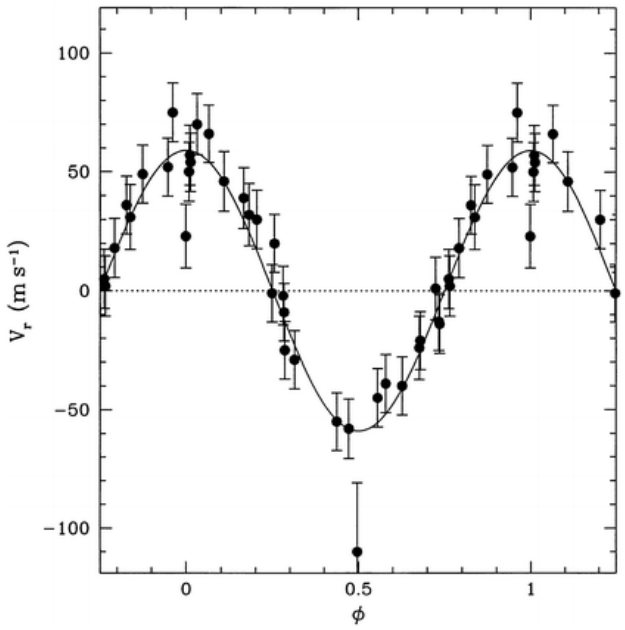

Figure 2. The variation of the radial velocity of 51 Peg (from Mayor M and Queloz D 1995 *Nature* **178** 355).

1. The orbital plane of the planet must be correctly oriented: for random orientations, the geometric probability p is $p = R_*/a$. For a Jupiter (an Earth) around a $1R_\odot$ star, this probability is 10^{-3} (respectively 0.5%).
2. The precision of the star's photometry must be better than the depth $\Delta F/F = (R_P/R_*)^2$ of the transit. For a $1R_{\rm Jup}$ ($1R_\oplus$) planet the drop is 1% (respectively 10^{-4}). In ground-based observations, the photometric precision is at best 0.1%. In space, it can reach a few 10^{-5}. Thus, while Jupiter-size planets can be detected in this way from the ground, one can detect Earth-sized planets from space. In fact, it is at present the only method capable of detecting and investigating further Earth-like extrasolar planets.

Late in 1999, the first planetary transit was detected from the ground (around the star HD 209458), leading to the first determination of the radius of an extrasolar planet; this transit was confirmed by an inspection of the photometric archives of the Hipparcos satellite.

Gravitational lensing

The planet can produce a gravitational amplification A_G of the light of background stars, increasing with the planet's mass and its distance to the observer. This amplification can reach factors up to 100 when the planet lies at several kiloparsecs, i.e. as far as the Galactic center. The GRAVITATIONAL LENSING method is thus suitable only for very distant planets, difficult to observe afterwards by any other method. Furthermore, a lensing event is seen only once and it is not possible to investigate a planet at 4 kpc any further by any other method. This makes the lensing method less attractive. Nevertheless, astronomers have recently shown by this method that less than 25% of stars have Jupiter-mass companions at distances larger than 3 AU.

First lessons from present findings

As often happens in science, what has been found was largely unexpected. The first discoveries of extrasolar planets have managed to produce great surprises and a few conclusions can already be drawn. There are three main lessons from these discoveries, all equally important.

First, the global result is that about 5% of main sequence stars have a giant planet at a distance less than 2 AU. Before 1995, astronomers had no idea whether planetary systems were very rare or not. There could, for instance, have been less than one planetary system for 1000 stars. By itself this knowledge is very precious for planetary formation theory. The theoreticians now have to explain this proportion. Also, it immediately raises a new, important question. This proportion being valid for giant planets, does it hold for telluric (i.e. small solid) planets? The latter could indeed *a priori* be very different as their formation and evolution mechanisms are significantly different. This question is of course important for future searches for life on Earth-like planets.

A second conceptually important consequence comes from the discovery of the first transitory planet HD 209458. Since a transitory body has been observed and its radius has been measured (giving a value 30% larger than Jupiter), it constitutes the first proof that the stellar wobble is due to a planet and not to other causes (such as stellar oscillation, small companion black hole,…). It also rules out an *a priori* possibility: that the

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

planet is a heavy (0.6 Jupiter mass) planet entirely made of solid rock instead of gas. In that case, its radius would have been ~0.3, instead of 1.3, Jupiter radii. Thus, from transits we can learn much about the planet constitution.

The third lesson is that these discoveries have given unexpected results.

1. While astronomers were expecting to find planets around main sequence stars, the first planets were discovered around stars where they were not expected, namely around pulsars. It is not clear how these planet-mass objects can be formed: have they survived the supernova explosion or have they condensed in the supernova remnant? If they were planets from the pulsar progenitor, they should have very eccentric orbits, while for PSR 1257+12 the eccentricity is almost 0. Indeed, because of the conservation of their angular momentum $J = [M_* a_P(1 - e^2)]^{1/2}$ and total energy $E_{\rm pot} + E_{kin}$ after the mass loss $M_{*1} \rightarrow M_{*2}$ during the supernova explosion, they acquire an eccentricity given by $1 - e^2 = M_{*1}(2M_{*2} - M_{*1})/M_{*2}^2$. Furthermore, the orbit remains bound only if $M_{*2} \geq M_{*1}/2$.
2. The first giant planets were found 100 times closer to their parent star than expected. Indeed, for main sequence stars with masses from $0.1M_\odot$ to $1M_\odot$, the planets were expected to form at a distance from 4 to 5 AU. This is the distance at which the equilibrium temperature is below 160 K, to allow for the formation of icy cores of giant planets. It was thus an incomprehensible surprise to find planets as close as 0.05 AU to their parent star. In fact the solution to this problem seems to lie in the notion of 'orbital migration' introduced 10 yr before the planets were discovered. When a planetary core has started to grow up to a mass M_P in a protoplanetary disk, it creates, by gravitational attraction of the surrounding gas and dust, a gap with a radius $R_H \approx a_P(M_P/M_*)^{1/3}$; this is the radius of the 'Hill sphere' inside which the gravitational attraction of the planetary core is larger than the attraction of the parent star. There are then tidal forces between the core and the inner and outer edges of the gap, whose imbalance depends on the difference in density between the edges. The imbalance can be such that these tidal forces pull the orbit toward the star.
3. Some of the planets have orbits with unexpectedly large eccentricities. This makes it unlikely that they were formed in a protoplanetary dust disk, since the internal dissipation circularizes the orbits of the dust grains. They were thus more likely to have formed in a way similar to very-low-mass stars, i.e. by gravitational condensation of the gas, with no solid core. For 16 Cyg B, the eccentricity comes perhaps from the perturbation by the companion star 16 Cyg A. Eccentricity of orbits can also be the result of migration: during their migration (at different rates) one planet can expel another from the system; from angular moment conservation, it then results that the resulting orbits must be very eccentric.

Future perspectives

These first discoveries have encouraged astronomers to accelerate their searches and many projects are at present ongoing or under study.

Future ground-based and space-based facilities

Radial velocity searches. ESO will make radial velocity searches in a dedicated program (to start in 2001) with the 3.6 m telescope at La Silla with a precision of 1–2 m s^{-1}. There is also a Swiss program, monitoring 800 stars on a dedicated 1.5 m telescope, that started in 1998, at La Silla. At the 10 m Keck telescope, Marcy *et al* have started to monitor 400 stars with a precision of 3 m s^{-1}. Several other groups conduct such radial velocity searches, or plan to do so, with more moderate precisions.

Astrometric search. The FAME astrometric mission, to be launched by NASA in 2004, is intended to measure during a few years the positions of millions of stars with a precision of 50 μarcsec (μas). It should detect up to a few hundred Jupiters. The Space Interferometric Mission (SIM) is a NASA project, devoted mainly to astrometry and, secondarily, to imaging. The nominal goal for astrometric precision is 4 μas. As far as extrasolar planets are concerned, this would give SIM the ability to detect Saturn-mass (Earth-mass) planets at up to 15 pc (respectively 5 pc). The GAIA project, if selected by ESA in the future, would measure the positions of 10^9 stars in the Galaxy with a precision of 1 μas (10 μas) for stars with $V = 5$ (respectively $V = 15$). For solar-type stars, it could detect 'big Earths' (with 10 Earth masses) around ~100 stars at up to 10 pc and Jupiter-mass planets at up to 200 pc around about 5×10^5 stars. In the latter case, if the proportion of ~5% of stars having planetary systems holds, one can estimate that GAIA would detect ~25 000 extrasolar Jupiters.

Imaging On the ground, large telescopes such as the Keck telescope, the VLT and the Large Binocular telescope will try to search for planets by imaging in the future, by different interferometric techniques. However, their imaging performances are yet not well known.

In space, the projects are more clearly identified (although the situation could change with new plans).

The NASA NGST Project (Next Generation Space Telescope), to be launched after 2007 if approved, is a large (~8 m) telescope. Its orbit is not definitely chosen; perhaps around the Earth–Sun Lagrange point L2. If a coronographic mode were to be implemented, it could detect Jupiters around nearby stars.

Other space projects, based on interferometric nulling, were initially motivated by exobiologic purposes. They did lead to the DARWIN project, presented in 1993 as an ESA cornerstone candidate, quickly followed by the NASA Terrestrial Planets Finder (TPF). DARWIN is, in its initial configuration, a free-flyer mission made of five 1.5 m telescopes separated by 20–100 m, while TPF is initially based on a rigid linear structure. The main difficulty encountered by these projects is that, in order to detect planets at 10 μm, it is necessary to avoid the IR thermal emission of the solar system's zodiacal dust; the only solution found to circumvent this difficulty is to send the mission to 5 AU from the Sun. A complete unknown is also the level of zodiacal IR thermal emission of other planetary systems. Extrasolar IR zodiacal light similar to the solar system's zodiacal light gives a background 300 times larger than the planet's emission. The example of 55 Cnc points out the danger that such backgrounds can even be 10 times larger than the solar system's zodiacal light. Another project, in the visible, has recently been suggested: the Epicurus project proposed by A Labeyrie to ESA. In the visible and near-IR range, the zodiacal light problem is avoided. A much more ambitious project is under study to make multipixel images of an extrasolar Earth-sized planet: the Planet Imager project, a multikilometer space interferometer which could be built around 2030 (do not forget that from now to 2030 there is the same time span as that from 1970 to today).

Transits. Programmes from space are under way, with different statuses.

- The Hubble Space Telescope carried out photometric monitoring in July 1999, continuously over 9 days, of 20 000 stars in the globular cluster 47 Tuc. It should have detected a few tens of Jupiters in close orbits. Preliminary results show that zero planets are detected; this may be due to the submetallicity of the cluster's stars.
- COROT is an ESA/CNES mission (to be launched in 2004) dedicated half to asteroseismology and half to planetary transits. It is in fact the only currently approved space mission largely dedicated to the search for extrasolar planets. With its 25 cm aperture, it should detect, during its two and a half years of operation, tens of planets with radii down to ~$2R_\oplus$ at orbital distances up to ~0.5 AU from their parent star. For M stars, some of these planets should fall in the 'habitable zone' of the star (defined as the distance at which the planet's temperature allows for liquid water).
- The KEPLER project is entirely devoted to the search for planetary transits. It is much more ambitious than COROT but is not yet approved. With its 1 m aperture and its 100 deg^2 field of veiw, it should be able to detect, after 5 yr of operation, a few hundred Earth-like planets in the habitable zones of stars.
- There is also a similar ESA project under study: Eddington.

Extrasolar planetary environments and comets. Given the extreme difficulty of detecting extrasolar planets, it seems premature to detect their surroundings such as PLANETARY RINGS etc and extrasolar COMETS. Surprisingly, most of these surroundings are detectable, some of them even more easily than planets themselves.

Rings. Rings of extrasolar planets have such a low mass (less than an Earth mass) that they have no observable dynamical effect on the star's motion. However, as shown by the example of Saturn's ring, they can be significantly more extended than giant planets (their surface being 4 times the projected surface of giant planets). They are thus obviously easier to observe by methods sensitive to the surface of objects to be detected, namely direct imaging and transits.

Satellites. Giant satellites of planets are, at least in the solar system, at most as large as telluric planets. Since to detect them by imaging it is necessary to separate them from the parent planet, the required separation power needs kilometric baselines in space.

The transit method is more promising and can be exploited in two different ways.

- Detection of the transit made by the satellite itself is marginally possible for giant (Titan-like) satellites in front of a low-radius (M or K) star monitored with a photometric precision of 10^{-4} or better (as is the case for the COROT mission and the Kepler project).
- Even if the satellite transit itself is not detected because of lack of photometric precision, it disturbs the timing of the transit of the giant planet by an amount $\Delta T_S \approx 15$ min (very easy to detect) for an Earth-mass satellite in orbit around a Saturn-like planet.

Magnetospheres. At least one planet in the solar system has a radio decametric emission stronger than that of the (quiet) Sun. This is probably due to a strong quasi-dipolar magnetic field of internal origin, producing an extended PLANETARY MAGNETOSPHERE in which particle acceleration takes place, inducing strong non-thermal radio emission.

These emissions would be detectable at 15 pc with the best receptors (Jupiter itself would be detectable at 0.5 pc). Planetary magnetic fields are usually attributed to turbulent rotation–convection motion of conducting material inside the core. Scaling laws predict a magnetic field of a few gauss for the already discovered extrasolar planets. Further in the future, a radio telescope on the dark side of the Moon would be free of anthropogenic

parasites and of ionospheric absorption. It would allow for radio detection below 10 MHz.

Comets. In the star β Pictoris, intense spectroscopic monitoring shows rapidly (on time-scales of days) varying absorption lines. One can interpret them in terms of absorption by infalling evaporating comets at a rate of about one infall per day. If this interpretation is correct, this method could succeed for this particular star because it is surrounded by an exceptional reservoir of small bodies, as shown by the presence of a dust disk. For random stars, it is easier to detect comets by the transit of their dust tail, in a way similar to the detection of planets. For an amount of comets equivalent to that of our solar system, the detection rate by this method is about one comet per month.

Search for life on extrasolar planets

Habitable zones. What could be called 'life' is the subject of an immense debate (Schneider 1998; see also LIFE ON OTHER WORLDS). Let us restrict ourselves here to the standard conservative choice of carbon-based organic chemistry on a solid planet with liquid water. The planet must be sufficiently massive to retain its atmosphere, but not so massive as to retain its hydrogen, which would be lethal for standard life. Its mass must then be between $0.1M_\oplus$ and $10M_\oplus$. With pressure conditions given by this mass range, liquid water can be present if the planet temperature is about 300 K.

A planet orbiting at a distance a around a star with a radius R_* and a temperature T_* acquires by heating an equilibrium temperature T_P given by

$$T_P = \frac{(1-A)^{1/4}}{\sqrt{2}} \left(\frac{R_*}{a}\right)^{1/2} T_*$$

where A is the mean 'albedo' (reflectance) of the planet surface. From equation (2), a planet having a temperature $\simeq 300 \pm 20$ K must be located at a distance a from the star given by (for $A = 0.55$) $a = 0.7R_*(T_*/300)^2$. Depending on the type of the central star, this distance runs from $\simeq 0.1$ AU for cool ($T_* = 3000$ K) dwarf stars to $\simeq 2$ AU for hot ($T_* = 6500$ K) larger stars. For hotter stars the habitable zone is larger than 2 AU, but they evolve too rapidly to have stable temperature conditions over the billions of years required for the development of life (unless one invokes less conservative scenarios).

Remote detection of signatures of life. Suppose that an Earth-like planet is discovered in the habitable zone of its parent star. Is it possible to detect the presence of life on it? The answer is that it is possible to detect spectroscopic signatures of what is perhaps due to complex organic chemistry. One can think of two types of signatures.

1. *Search for oxygen.* The first type of approach rests on the observation that on Earth all the molecular oxygen and ozone in the atmosphere are of biogenic origin. To then separate the planet from its parent star, an interferometer in space with a baseline of at least 20 m is required (the DARWIN project).

However, this method suffers from at least one artefact due to the photodissociation of water under some conditions (such as the continuous supply of water by a large quantity of infalling comets).

In addition, oxygen delivery is a secondary consequence of Earth-type photosynthesis and we do not know to which extent it is accidental or universal. For instance, there are many photosynthetic bacterial species on Earth which do not deliver oxygen as a byproduct of their photosynthetic activity (producing sulfur instead).

2. *Search for chlorophyll.* A more general signature rests on the remark that, whatever the details of an extrasolar biochemistry might be, it must make use of a molecular converter which absorbs the stellar light in the intense part of its spectrum to transform it into chemical energy. On Earth, this converter is chlorophyll, but it could be other molecules on other planets. On Earth, the chlorophyll absorbs up to 80% of light in the band 400–700 nm. It would be seen as an absorption band of a few per cent in the planetary spectrum at wavelengths where the star is the brightest. To minimize the risk of confusion with artefacts (for instance absorption bands of silicates), the amount of absorption can be correlated with the planet's seasons.

Conclusion

For the first time we have a clear answer to a 2300 yr old question: 'are there somewhere [i.e. around other stars] other worlds like ours?' (EPICURUS 300 BC). The first discoveries have been full of surprises and we should be prepared for the unexpected.

In this new era of astronomy, one can already design a plan for the long-term future with well-identified steps in a clear global strategy for the entire coming century, with even a tentative agenda:

(a) first images of extrasolar planets (around 2005);
(b) detection of Earth-like planets (2005);
(c) search for spectral signatures of life (2010–15);
(d) multipixel imaging of extrasolar planets (>2025);
(e) multipixel spectroscopy of extrasolar planets (>2030).

In the second half of the century, when the most interesting planets (possibly with signs of biological activity) will have been identified, the pressure will become strong to design a mission to go there (in one way or another). Let us not forget that future astronomers born today will most likely experience these times

around 2100. A prospective view beyond that would be pure speculation.

Web update (15 August 2001)

A second planet has been found orbiting the star 47 Ursae Majoris located in the asterism the Plough or Big Dipper in the constellation of Ursa Major. The new planet is at least three-fourths the mass of Jupiter and orbits the star at a distance that, in our Solar System, would place it beyond Mars but within the orbit of Jupiter.

In addition, new observations from the Submillimeter Wave Astronomy Satellite (SWAS) provide the first evidence that extra-solar planetary systems contain water, a molecule that is an essential ingredient for known forms of life. From its vantage point in orbit above the absorbing effects of water in Earth's atmosphere, SWAS is capable of detecting the distinctive radiation emitted by water vapor in space.

An aging giant star designated by astronomers as IRC+10216, also known as CW Leonis, located 500 light-years (almost 3000 trillion miles) from Earth in the direction of the constellation Leo, is apparently vaporizing a surrounding swarm of comets, releasing a huge cloud of water vapor. The observations of water vapor around IRC+10216 suggest that other stars may be surrounded by planetary systems similar to our own. Over the past decade, more than 50 stars have been shown to have large planets in orbit around them, but little is known about the composition of those planets.

Breaking news update (31 January 2002)

Observations by NASA's Hubble Space Telescope of the gas-giant planet orbiting the yellow, Sun-like star HD209458, 150 l.y. from Earth have revealed the presence of sodium in light filtered through the planet's atmosphere when it passed in front of its star as seen from Earth. The planet was discovered in 1999 by its subtle gravitational pull on the star. The planet is 70% the mass of Jupiter. Its orbit is tilted nearly edge-on to Earth, which allows repeated transit observations. The planet is only about 6 million km (4 million mi) from the star. At this distance the planet's atmosphere is heated to around 1000 K.

At the time of this update 66 extrasolar planetary systems are confirmed, consisting of 74 planets and 7 multiple planets systems. See http://www.obspm.fr/encycl/catalog.html. Among recent discoveries are three Jupiter-sized planets travelling in circular orbits similar to that of Earth and Mars in our own solar system.

Extreme Ultraviolet Explorer (EUVE)

NASA spacecraft launched on July 7, 1992 to carry out a full-sky survey in the extreme ultraviolet range of the spectrum. It carried three EUV telescopes, each sensitive to a different wavelength band. A fourth telescope performed a high sensitivity search of a limited sample of the sky in a single EUV band.

EUVE re-entered the Earth's atmosphere at approximately 23:59 UTC on January 31 2001. According to calculations made by the United States Space Command Space Control Center, EUVE re-entered the atmosphere over central Egypt. The object was not designed to survive re-entry intact and was expected to break apart and mostly burn up in the atmosphere. U.S. Space Command cannot confirm if any pieces survived re-entry. Science operations ended in December 2000. During its eight years in orbit, EUVE was the first astrophysics mission to explore the extreme ultraviolet and helped to bridge the gap in our understanding of this previously unknown spectrum. EUVE observed more than 1,000 nearby sources, including more than three dozen objects outside the Galaxy.

Eye Relief

The distance between eyepiece and the exit pupil. In the case of a compound eyepiece consisting of two or more lenses, the eye relief is the distance from the final lens to the exit pupil. For comfortable visual observing, the eye relief should be in the region of six to ten millimeters.

See also: exit pupil, eyepiece, field of view, magnification.

Eyepiece

A magnifying lens used to view and enlarge the image produced at the focus of a telescope. For any given telescope, the magnification achieved is inversely proportional to the focal length of the eyepiece. A telescope used for visual work will normally have a range of eyepieces of, for example, 40 mm, 25 mm, 12 mm and 6 mm focal lengths. Used with a telescope of focal length 1200 mm, these eyepieces would produce magnifications of $\times 30$, $\times 48$, $\times 100$ and $\times 200$ respectively.

The eyepiece is normally mounted in a short tube (the drawtube) that can be slid in and out to enable the sharpest focus to be achieved. For visual use, the eyepiece is normally placed beyond the focal plane of the telescope at a distance such that the rays emerging from the eyepiece from each part of the image enter the eye along parallel paths. The eye is then relaxed (as if looking at an infinitely distant object) and less likely to become tired. For an eyepiece consisting of a single lens, this condition is achieved when the distance between the focal plane of the telescope and the eyepiece is equal to the focal length of the eyepiece.

The main parameters of an eyepiece are focal length, exit pupil, eye relief, and apparent angular field of view. Focal length determines the magnification achieved. The exit pupil is a circle through which all rays emerging from the eyepiece pass, and eye relief is the distance between the rear of the eyepiece to the exit pupil. For comfortable viewing this should normally be in the region of 6 to 10 mm. The apparent angular field of view, or acceptance angle, is the angular diameter of the circle of vision that can be seen when the eye is placed at the exit pupil. Apparent fields of view for eyepieces range from about 30° to as much as 85°, depending on the design. The observed field of view (the angular diameter of the region of sky that is visible through the telescope) is equal to field of view of the eyepiece divided by the magnification. For example, if an eyepiece with an acceptance angle of 50° produces a magnification of $\times 100$, the observed field of view will be 0.5° (approximately equal to the apparent diameter of the Moon).

There are many different types of eyepiece. Although the simplest is a single biconvex lens, an eyepiece of that kind suffers markedly from various aberrations, in particular chromatic and spherical aberration. In practice, eyepieces consist of at least two lenses, a field lens, which accepts rays of light from the telescope objective or mirror, and an eye lens, from which light emerges into the eye. Huygenian and Ramsden eyepieces consist of two plano-convex lenses (in the former case, the field lens is placed inside the focal plane of the telescope and the image is formed, inconveniently, between the two lenses). Although cheap to produce, they suffer from chromatic aberration and have modest fields of view (35°–45°). The Kellner is similar to the Ramsden, but uses as its eye lens an achromatic doublet, which greatly reduces chromatic aberration. Better correction for aberrations, good fields of view (about 50°) and good eye relief are provided by more complex eyepieces such as the orthoscopic (in which the field lens is a triplet and the eye lens plano-convex) and the Plössl (which consists of two identical achromatic doublets). For certain purposes (for example, observing star clusters or nebulae of large angular size), wide-field eyepieces such as the Erfle or Nagler are advantageous. Eyepieces of this kind, which consist of many elements (typically six or more), offer angular fields of view of up to 85° but are very expensive to produce.

Faber–Jackson Relationship

A correlation between the luminosity of an elliptical galaxy and the velocity dispersion (the spread in velocities) of the stars in its central regions that was established in 1976 by S M Faber and R E Jackson. The light that emerges from the central regions of an elliptical galaxy is the combined light of large numbers of stars, some of which (measured relative to the center of the galaxy) are approaching the observer and others receding. Consequently, the Doppler effect broadens the lines in the galaxy's spectrum by an amount that depends on the spread of velocities among its constituent stars (lines in the spectra of approaching stars are blue-shifted to shorter wavelengths, lines in the spectra of receding stars are red-shifted to longer wavelengths, and the resulting lines in the spectrum of the galaxy are spread out over a range of wavelengths). The velocities of its constituent stars, and hence the velocity dispersion, depend on the mass of the galaxy (the higher the mass, the greater the velocities) and, as a general rule, the higher its mass, the more stars the galaxy contains. Consequently, it is logical that there should be a link between velocity dispersion and luminosity.

Fabri [Fabry], Honoré (1607–88)

Born in Virieu-le-Grand, Dauphiné, France, a Jesuit, he held posts in a variety of cities in France and in Rome, where he was briefly imprisoned for unorthodoxy. He was an astronomer, physicist and mathematician and studied Saturn's rings, disputing about their nature with HUYGENS for five years. Discovered the Andromeda nebula, developed a theory of tides which was based on the action of the Moon and pioneered calculus.

Fabricius, David (1564–1617) and Fabricius, Johannes (1587–1616)

Lutheran pastor and astronomer in Osteel, East Frisia (northwest Germany), discoverer (1596) of the first known variable star, *mira stella* ('wonderful star'), now simply Mira (Omicron Ceti). Fabricius observed the star at its brightest and thought it was a nova, after which Holwarda noticed that a star in Cetus cataloged by PTOLEMY and TYCHO was missing but then it reappeared. Eventually the long periodic cycle of Mira was recognized. In 1611, his son Johannes returned home from the Netherlands with a telescope. Johannes discovered spots on the disc of the rising Sun, which the father and son investigated, first by direct observation, then switching to a camera obscura because of the Sun's brightness. They discovered how the spots rotated behind the Sun and back into view. Johannes wrote an un-influential tract on Sunspots, *De Maculis in Sole Observatis, et Apparente earum cum Sole Conversione Narratio* ('Narration on Spots Observed on the Sun and their Apparent Rotation with the Sun'), which was overshadowed by SCHEINER's similar discoveries a year later. Johannes died young, and David was killed with a shovel a year later by an angry peasant, whom he had accused of stealing a goose.

Faculae

Patches of enhanced brightness in the solar photosphere that are often seen in white light images of the Sun. They can normally be observed only when located relatively close to the edge of the visible disk (the limb) where the background brightness of the photosphere is less intense than at the center of the disk. They form inside active regions where localized magnetic fields heat their material to temperatures several hundred kelvin higher than that of their surroundings. Although often associated with sunspot groups, they may also be seen before spots emerge and after they disappear.

Fallows, Fearon (1789–1831)

English astronomer, born in Cockermouth, Cumberland. Disenchanted with university life at Cambridge, he won the job of the first director of the Royal Observatory at the Cape, in South Africa, to provide navigational and time information for the ships of the Royal Navy that called into the harbor. He established the observatory at the base of Table Mountain, in what is now Observatory, a suburb of Cape Town, and began observing after a series of misfortunes and tribulations with the Admiralty, builders, staff, servants, his wife and relatives, accidents and snakes. His health suffered. He died aged 42 of the effects of scarlet fever, and is buried in the observatory grounds. A sad story.

False Cross

The asterism formed by the four stars δ and κ Velorum, and ε and ι Carinae, all of the second magnitude, which make up a cross of about $10^\circ \times 6^\circ$. It is so named because it is sometimes mistaken for the Southern Cross (Crux) by observers unfamiliar with the southern sky. There is a superficial resemblance, but Crux is more compact (about $7^\circ \times 5^\circ$) and comprises rather brighter stars. The two crosses can in fact be quite easily distinguished, as the False Cross appears to recline, whereas the long axis of the Southern Cross runs almost exactly north–south, and the latter has the additional indicator of two bright stars (α and β Centauri) to the east of and in line with its short axis.

Far-Infrared and Submillimetre Telescope (FIRST)

European Space Agency 'Cornerstone' mission to be launched in 2007. Carries a 3.5 metre diameter mirror, the largest ever used for an infrared space telescope. Its three instruments—two cameras and a high-resolution spectrometer—will observe far-infrared and submillimetre emissions from gas and dust heated by young stars, and should detect galaxies forming in the very early Universe. The instruments will be cooled close to absolute zero (−273 °C) using liquid helium cryostat technology developed for the ISO mission.

Far-Ultraviolet Spectroscopic Explorer (FUSE)

The first large-scale space mission to be fully planned and operated by a US academic establishment—Johns Hopkins University in Maryland. Launched June 1999. Began as a NASA-managed project in the mid-1980s, but later restructured to reduce cost and development time. Designed for high resolution spectroscopic studies at far-ultraviolet wavelengths. It will examine hydrogen and deuterium gas clouds between stars in the Milky Way and nearby galaxies, giving new information about galaxy evolution and star formation. (See also EXPLORER.)

Fermi, Enrico (1901–54)

Italian physicist, created the first controlled chain reaction, founded Argonne National Laboratory. His work on the properties of electrons (spin-half particles like electrons are called fermions after him, and the study of their properties is called *Fermi–Dirac statistics*) enabled the pressure source in white dwarf stars to be identified, and white dwarf star properties to be calculated by CHANDRASEKHAR. Articulated the *Fermi paradox*, suggesting that the time-scale for a space-faring race to colonize a galaxy was small compared to the life of a galaxy, and so in any given galaxy all suitable planets should have been occupied; but this seems not to have been the case for the Earth.

FG Sagittae (FG Sge)

FG Sge ($\alpha = 20^\circ11'56''$, $\delta = +20^\circ20'04''$, epoch = 2000) is a very peculiar giant star undergoing extremely rapid evolutionary changes and nucleosynthetic processing. It has evolved at a remarkable pace over the last century changing among other properties its appearance from a hot (O-type) star to a luminous, cool (K-type) giant today. FG Sge is classified as a 'born-again giant' currently experiencing its second stage as an asymptotic giant branch (AGB) star. The rapid and rare metamorphosis is likely the result of re-initiated nuclear burning when the star was approaching the domain of stellar embers as a WHITE DWARF. The newly generated nuclear energy has ballooned the star back to giant dimensions and simultaneously caused the cooling of the stellar surface. As one of just a few such known stars, FG Sge provides astronomers with an unusual opportunity to study stellar evolution and nucleosynthesis in real time. Furthermore, it resembles the R CORONAE BOREALIS (R CrB) STARS and thus may shed light on their unclear immediate ancestry.

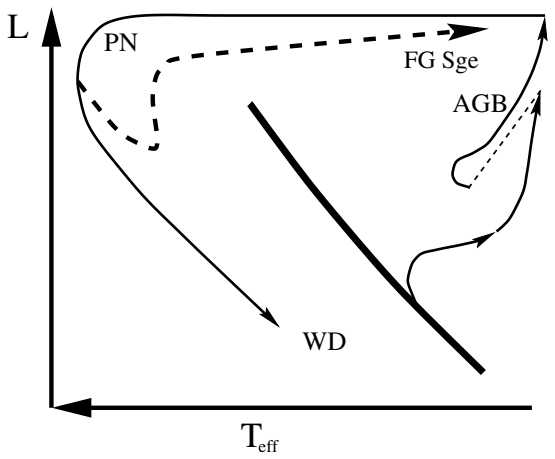

Figure 1. A schematic Hertzsprung–Russell diagram showing the likely evolution of FG Sge in terms of surface temperature and luminosity. Rather than fading to become a white dwarf (WD) after having departed from the asymptotic giant branch (AGB) and passing through a planetary nebula (PN) phase, the star has experienced a final He-shell flash causing it to briefly return to the AGB regime for the second time.

Born-again giants

Normally stellar evolution proceeds on time-scales of millions or billions of years. Notable exceptions are SUPERNOVAE, for example, though such cataclysmic events only represent the ultimate end as normal stars. To witness stellar evolution without a simultaneous complete disruption of the star on a time-scale more appropriate to the lifetimes of humans is consequently exceptionally rare. 'Born-again giants', such as FG Sge, offer a unique opportunity to study stellar evolution and nucleosynthesis during the very act, which gives important information as to how the late stages of evolution for stars similar to the Sun may proceed.

Towards the end of the AGB phase, stars of intermediate mass (a stellar mass on the main sequence of $M_* \approx 1$–$9M_\odot$) successively experience relatively long periods of quiescent hydrogen burning and brief periodic outbursts of helium burning. The latter phenomenon is called thermal pulses or 'He-shell flashes', as the He burning is thermally unstable. The thermal pulses during the AGB are responsible for substantial mixing of the interior by the development of convective shells (dredge-up), which in turn leads to further nuclear processing. Such dredge-ups are believed to eventually turn the AGB star into a CARBON STAR. The thermal pulses also extinguish the outer H-burning shell by pushing it outwards to lower temperatures. Once the He burning has died down, H burning is once again ignited and the story repeats itself after about 10^4–10^5 years.

Finally, however, due to the ever-decreasing envelope mass resulting from the intense mass loss and nuclear processing, the AGB stage is terminated. The dispersal of the cooler envelope allows the hotter core to be glimpsed, causing the star to evolve rapidly towards hotter surface temperatures in the HERTZSPRUNG–RUSSELL (HR) DIAGRAM. The still present nuclear energy production soon fizzles out, leaving the star to cool as it descends the white dwarf cooling track. Eventually it fades to oblivion when no nuclear energy is able to replace the thermal energy lost as an ever-more faint stellar ember. A schematic representation of a typical post-AGB evolution is shown in figure 1.

Though the above scenario is the most likely chain of events, descending the white dwarf cooling track may not be a dead-end. Theoretical estimates suggest that in about 10% of the stars going through a PLANETARY NEBULA stage, the pre-white dwarf will experience one more He-shell flash, causing an additional loop in the HR diagram. Due to the heating of the interior during the gravitational contraction of the core, the temperature may rise sufficiently to again trigger He burning. The liberated nuclear energy is sufficient to expand the star back to its former glory as a cool, luminous giant. If the outer H-burning shell is still active, the final He-shell flash will only cause the star to swell up but not bring down the outer envelope gas to the high temperatures of the interior due to the entropy barrier posed by the H burning. However, if H burning has ceased, no such obstacle prevents an almost complete ingestion of the still H-rich envelope, which in turn triggers H burning as well as associated nucleosynthesis and mixing with the interior. In such a case one can expect large modifications of the surface chemical composition, in particular regarding the elements H, Li, C, N and the slow neutron capture (s-process) elements.

The lifetime of such a rejuvenated giant is, however, short since quiescent He burning is never established. Within 100–1000 years—depending on the remaining envelope mass—the born-again giant will trace back its

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

former path when the stellar envelope will again be dispersed to finally become a white dwarf, this time a point of no return. The short lifetimes of born-again giants ensure that this phenomenon will be an observational rarity, in spite of the relatively many stars which are expected to undergo such a phase. Since the final thermal pulse may occur during a planetary nebula phase, this scenario can naturally explain the presence of nebulae surrounding some cool, luminous stars in the vicinity of the AGB, which otherwise would be difficult to understand.

The evolution of FG Sge

The rapid evolution of FG Sge during the twentieth century can be understood as the result of a final He-shell flash in a post-AGB star, as illustrated in figure 1. The best evidence that FG Sge is indeed a born-again giant is its surrounding nebula Henize 1-5, which directly implies that FG Sge very recently must have been a hot planetary nebula nuclei (with a surface temperature $T_{\rm eff} \geq 50\,000$ K). It is not possible to conclude exactly when the thermal pulse occurred but it most likely happened towards the end of the nineteenth century. Since then the star has been evolving towards cooler surface temperatures as a result of the overall expansion. Due to the cooling, the star has steadily become visually brighter; the visual magnitude decreased from $\approx 14^{\rm m}$ in 1880 to $\approx 9^{\rm m}$ in 1990. As yet it is unclear whether it has also increased in bolometric luminosity since the lower temperatures have shifted most of the emergent flux to optical wavelengths. According to theoretical calculations, the evolution towards the AGB regime proceeds at essentially constant luminosity after an initial rapid fading and subsequent brightening (not observed in the case of FG Sge). The evolutionary time-scale of about 100 years to reach the AGB again is consistent with the theoretical estimates for a current stellar mass of $M_* \approx 0.6 M_\odot$ (implying a mass on the main sequence of about $3 M_\odot$).

Historical spectra revealed that FG Sge was a hot star ($\approx$O3, with $T_{\rm eff} \approx 43\,000$ K) in 1880, from which it has continually evolved towards later spectral types (see CLASSIFICATION OF STELLAR SPECTRA). Today it is roughly a K2 giant, but exact classification is complicated by its extraordinary rich and peculiar stellar spectrum. To attribute a surface temperature of the star from say, 1980, until today is therefore rather uncertain, though various photometric and spectroscopic estimates suggest $T_{\rm eff} \approx$ 5000–6000 K. Accompanying the changes in appearance, the pulsational period has increased from around 5 days in the 1930s to about 100 days during the early 1990s. This can be qualitatively understood as a consequence of the expansion of the star, probably from not much bigger than the Earth to a giant perhaps 100 times the size of the Sun. From a pulsational analysis, a stellar mass of $M_* \approx 0.8 M_\odot$ can be deduced but unfortunately such estimates for FG Sge are still hampered by uncertainties.

It is not clear whether the final He-shell flash occurred before or after H burning had been terminated. Substantial modifications of the surface elemental abundances can only be expected in the latter case. There are indications that the amount of the *s*-process elements (e.g. Y, Zr, Ce and La) in the surface layers increased significantly by a factor of about ten within just a few years around 1970. Furthermore, during the 1980s FG Sge turned into a carbon star, as evidenced by the appearance of strong bands of molecular carbon (C_2) in the spectrum. Only in one other star, the similar born-again giant SAKURAI'S OBJECT, has direct evidence for current nucleosynthesis and mixing been witnessed. These observed hints of mixing suggest that H burning had already ceased before the final thermal pulse, but the details are far from properly understood.

Such surface abundance alterations are only predicted to occur at lower surface temperatures when the outer convection zone extends into layers in which nuclear processing has modified the chemical composition. It is also difficult to explain the surface enrichment of *s*-process elements prior to carbon, as theoretically one would expect the two to occur simultaneously. Furthermore, hydrogen is clearly still present in large amounts in the surface layers, while it is expected that during the ingestion of the envelope, a large portion of the present hydrogen should be burnt through CNO processing. There are indications that FG Sge may be modestly H deficient, suggesting an incomplete ingestion of the H-rich envelope, but this remains to be convincingly verified. In the alternative scenario in which H burning was still active when the thermal pulse occurred, any modifications of the surface abundances are not possible to explain without invoking other, more speculative, processes.

In August 1992 FG Sge suddenly experienced a drastic decline. Within a few weeks the star faded in the visual by more than four magnitudes. Closely thereafter an infrared excess, presumably related to circumstellar dust, was discovered which had not been present a few years earlier. The two events are therefore probably related: dust had started to condense around the star, which obscured the visual photosphere. The behavior has continued since 1992 to the present day with slow recoveries toward normal light interrupted by further rapid visual declines, as seen in figure 2. The star has, however, not yet fully returned to its initial brightness before the fadings were first observed. The variability suggests that the dust formation only occurs in localized patches rather than simultaneously around the whole star, and that fadings are only observed if the condensation happens to take place along the line of sight. This behavior closely resembles the visual variability of the R CrB stars, into which FG Sge may currently be evolving. The details behind the dust formation are poorly understood, both in FG Sge and the R CrB stars, but it is presumably related to stellar mass loss, as evidenced by the appearance of CO absorption from circumstellar gas in connection with the first fading of FG Sge. The apparent congruity between the timing of the onset of the declines and the pulsational phase of the star is suggestive of the existence of a causal connection, and further that the dust forms close to the stellar surface.

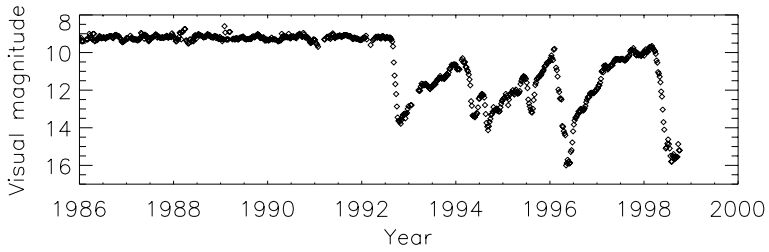

Figure 2. Visual magnitude estimates of FG Sge from 1986 to the present showing the drastic R CrB-type visual variability which started in August 1992. The data have been kindly provided by the AAVSO international database based on observations of variable star observers worldwide. The measurements have been averaged over five-day periods for the sake of clarity.

Related objects

Though FG Sge is clearly a truly unusual object it is not unique. There are at least two other stars which have been observed to undergo a born-again giant phase, and there are others which are suspected to recently have experienced a similar evolutionary stage. Both V605 Aql (Nova Aql 1919) and the recently discovered Sakurai's object have experienced a final He-shell flash during the twentieth century, and in fact evolved on an even shorter time-scale than FG Sge.

V605 Aql was initially classified as a NOVA when it brightened by more than four magnitudes between 1919 and 1921, before it soon faded to obscurity again. The rapid unfolding of events unfortunately has prevented the outburst phase from being studied carefully with modern instrumentation. Today the star is surrounded by the planetary nebula Abell 58, which contains evidence that V605 Aql indeed was a born-again giant recently. The outer parts are H-rich but the central knots of Abell 58 are H-deficient, which suggests that V605 Aql actually became H-deficient in connection with the final He-shell flash. The significantly faster evolutionary time-scale of just a few years compared with FG Sge, indicates that the stellar mass is higher, perhaps as high as $1.0 M_{\odot}$.

Another related object is Sakurai's object, which promises to hold important clues to the understanding of the born-again giant phenomenon. It was discovered in 1996 but had probably experienced its final He-shell flash a couple of years earlier, unnoticed. It has already cooled down to similar temperatures as FG Sge. More dramatically, it shows clear evidence of current mixing and nucleosynthesis which must have occurred subsequent to the thermal pulse. Since discovery, the surface abundance of hydrogen has decreased by a factor of ten while both the amount of lithium and *s*-process elements for example have increased by similar factors. These alterations are likely the result of H-burning, *s*-processing and Li-production through the Cameron–Fowler Be-transport mechanism. Furthermore, Sakurai's object has recently started to show visual variability similar to the R CrB stars and the appearance of an infrared excess, like FG Sge. Its even faster rise-time in brightness suggests it has a higher mass, likely similar to V605 Aql. Sakurai's object is also surrounded by a faint planetary nebula.

Furthermore, FG Sge seems to resemble the R CrB stars in terms of the visual variability with occasional drastic fadings. FG Sge has, however, not yet been shown to be H-deficient which is the other defining property of this group, though there are indications it may be. FG Sge may thus be evolving into an R CrB star. A study of its elemental abundance distribution is therefore expected to reveal whether it is in fact linked to these stars. Such an analysis is of great importance but is unfortunately encumbered by the complexity of the stellar spectrum. Further support for the hypothesis comes from Sakurai's object which not only shows typical R CrB variability but also a very similar chemical composition, suggesting a common evolutionary background.

Bibliography

FG Sge has attracted a great number of studies due to its special significance in terms of stellar evolution. The historical evolution of FG Sge is discussed in the following recent articles:

Field of View

The angular diameter of the area of sky that is visible through a telescope. When a telescope is used visually, this equates to the area of sky that can be seen when the eye is placed at the exit pupil of the eyepiece. The apparent angular field of an eyepiece is its acceptance angle: the apparent angular diameter of the circle of vision that can be seen when the eye is placed at the exit pupil. Typically this is about 40°, but, for wide-field eyepieces, can exceed 70°. The field of view of the telescope (θ) is related to the apparent field of the eyepiece (θ') as follows: $\theta = \theta'/M$, where M is the magnification.

For most telescopes, the field of view is less than one degree, a few tenths of a degree being typical. Schmidt telescopes, however, have fields of view of up to ten degrees.

Filament

A long, dark absorption feature seen against the solar disk in monochromatic light (light of one particular wavelength). Filaments are clouds of gas, with temperatures in the range 5000 K to 10 000 K, and lengths ranging from tens of thousands to hundreds of thousands of kilometers, which are suspended above the chromosphere by magnetic fields. They are normally located along the boundary between regions of opposite magnetic polarity on the solar surface (the 'neutral line').

Filaments appear dark because they absorb light from the background solar disk. Although they also emit light (they radiate an emission line spectrum) they are much fainter than the disk. For example, when viewed in the hydrogen alpha line (of wavelength 656 nm), a typical filament has no more than 10% of the brightness of the disk and appears dark by contrast with its surroundings. However, when solar rotation carries a filament across the edge of the solar disk, it then appears as a bright feature (a prominence) against a dark background.

Most filaments have lifetimes of about a month, but larger ones survive for several months. Occasionally a filament will erupt outwards and disappear within a few hours, such an event being called a 'sudden disappearance'. If the rising filament crosses the solar limb (the edge of the visible disk) it becomes visible as an eruptive prominence.

Filar Micrometer

A device that is used for the accurate visual measurement of the angular separation and relative orientation of two neighboring astronomical objects, such as the two component stars of a visual binary. It consists of a fixed 'horizontal' wire and two 'vertical' wires (i.e. orientated at right angles to the 'horizontal' wire), one of which is fixed and the other movable, the movable wire being adjusted in position by turning a finely threaded screw. The position of the movable wire is read off from a finely graduated drum that is rotated by the screw. The wires are positioned at the focal plane of the telescope and viewed by an eyepiece in which the wires and the astronomical objects are both sharply in focus. The entire micrometer assembly can be rotated around the optical axis of the telescope, its orientation being indicated on a finely graduated circular scale.

To make a measurement of the separation between two stars, the micrometer is rotated until one of the fixed wires (the 'horizontal' one) lies along the line between the two stars. The telescope is then adjusted until one of the stars lies on the intersection of the two fixed wires. The reading on the scale is noted. The movable wire is then shifted along until it intersects the second star, and a second reading taken. The difference in readings gives the linear distance through which the wire has moved. If the focal length of the telescope is known, the angular separation that corresponds to the measured linear separation can then be calculated. The orientation (or position angle) of the line joining the two stars is read from the circular scale.

Filterbanks

Filterbanks are instruments which divide the signal from a radio telescope into a number of frequency channels and measure the power in each of the channels. The output of the filterbank is a stream of digital data sent to a computer for analysis. Filterbanks can take several forms including analog filterbanks, digital filterbanks, fast Fourier transform (FFT) machines and software filterbanks. These different types of backend use very different means to accomplish essentially the same signal processing goals. Correlators can also be used as filterbanks (see the articles on CORRELATORS and PULSAR BACKENDS for more information).

Filterbanks are most commonly used to observe radio pulsars. A brief summary of the observational properties of pulsars will serve as an example of the use of filterbanks and also of how they work. For more information, see the article on PULSARS.

Pulsars and dispersion

Pulsars—highly magnetized rotating neutron stars—are observed as very regular pulses of broadband amplitude-modulated radio noise. These flashes of radio waves can be thought of as beams from a cosmic lighthouse sweeping through the Galaxy; when the beam intersects the Earth we see the pulsar's flash, and then it disappears until the beam comes around again. A pulsar's broadband non-thermal emission is characterized by a power-law radio spectrum

$$S \propto \nu^{-\alpha} \tag{1}$$

where S is the flux density (power per unit area per unit frequency), ν is the frequency and α ($\sim$2) is the spectral index.

The pulses of radio waves are emitted nearly simultaneously at all frequencies, but the interstellar medium (ISM) causes the different frequencies to propagate through space at different speeds (see INTERSTELLAR MATTER). Because of free electrons in the interstellar medium the signal at a lower frequency travels slower, and is therefore detected by telescopes later than that at a higher frequency. This dispersion is similar to the dispersion of white light into a rainbow of colors when it passes through a prism, and is the result of a medium having a frequency-dependent index of refraction. The propagation speed of the pulse (group velocity) as a function of frequency is given by

$$v_{\mathrm{g}} = c\left(1 - \frac{n_{\mathrm{e}}e^2}{\pi m_{\mathrm{e}}\nu^2}\right)^{1/2} \tag{2}$$

where c is the speed of light in a vacuum, n_{e} is the density of free electrons (assumed small), and e and m_{e} are the charge and mass of an electron respectively.

Dispersion greatly complicates observations of radio pulsars. At two given frequencies, the noise pulses from a pulsar will arrive at different times, separated by an amount proportional to the dispersion measure (DM), which is the integrated electron column density along the line of sight to the pulsar (DM $\equiv \int_0^d n(s)\,\mathrm{d}s$, expressed in units of pc cm^{-3}). Over a narrow bandwidth $\Delta\nu$, the time delay in seconds due to dispersion is given by

$$\Delta t_{\mathrm{s}} \simeq 8300\mathrm{DM}\Delta\nu_{\mathrm{MHz}}\nu_{\mathrm{MHz}}^{-3} \tag{3}$$

where $\Delta\nu_{\mathrm{MHz}}$ and ν_{MHz} are the bandwidth and observing frequency measured in megahertz. Figure 1 illustrates dispersion; the pulse arrival time varies by about a quarter of the pulse period over the observed bandwidth.

While dispersion complicates pulsar observations, it is not without benefit. By measuring the DM from the pulse time delay between different frequencies, we can estimate the distance to a pulsar based on our knowledge of the density of free electrons in the Galaxy in the direction of the pulsar. The density of electrons is higher in the Galactic disk, so generally speaking a given DM implies a shorter distance to a pulsar in the disk than to one at high Galactic latitude. Also, we observe a higher density of electrons toward the Galactic center than toward the outer Galaxy.

Filterbanks

The dispersive effects of the ISM discussed in the previous section demonstrate the need for pulsar filterbanks. The pulse profile (intensity as a function of time or pulse phase) observed in a bandwidth $\Delta\nu$ will be smeared in time by an amount Δt according to equation (3) (this smearing can be thought of as a convolution of the intrinsic pulse profile with a boxcar or top-hat function of width Δt). In order to resolve the details of the pulsar's light curve, we would like to have $\Delta t \ll P$, where P is the pulse period; this restricts us to small bandwidths. However, the signal-to-noise ratio increases as the square root of the bandwidth, and pulsars are weak sources, so we desire large bandwidths. The solution to this problem is to observe the pulsar in a number, n_{chan}, of narrow channels, each with bandwidth $\Delta\nu$. This gives the desired small Δt corresponding to a single channel bandwidth $\Delta\nu$, in addition to the increased signal-to-noise ratio corresponding to a total bandwidth $B = n_{\mathrm{chan}}\Delta\nu$. To correct for the dispersive delay between channels, an appropriate time offset is applied to each channel's output before the various frequency channels are combined. This signal processing solution is known as incoherent dedispersion; information about individual frequency components inside a single channel is destroyed by this method.

The number of channels in a filterbank is a primary factor in its complexity and cost, so n_{chan} is an important design parameter. The total bandwidth B is set by the telescope receiver, and it is generally desirable for the backend instrument to use all available bandwidth to maximize the signal-to-noise ratio. The maximum DM and Δt are set by science goals, with Δt being a small fraction of the minimum pulsar period a filterbank is

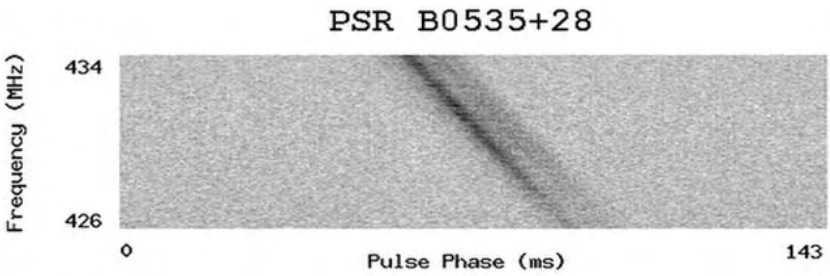

Figure 1. Dispersed pulse profile. The dispersed integrated pulse profile of PSR B0535 + 28, observed over an 8 MHz bandpass in 128 separate frequency channels with the Penn State Pulsar Machine at the Arecibo Observatory. Darker grays represent higher flux levels. Note that the pulse arrives significantly later at lower frequencies. This pulsar has $P = 143$ ms and DM $= 39.7$ pc cm^{-3}.

designed to study. From equation (3) we can see that the required number of channels for a filterbank operating at a central frequency ν is given by

$$n_{\rm chan} \simeq 8300 \frac{B_{\rm MHz} \rm DM}{\Delta t_{\rm s} \nu_{\rm MHz}^3}. \quad (4)$$

A filterbank can be thought of as a set of $n_{\rm chan}$ radio tuners working in parallel. Each tuner gets an identical input from the telescope (the antenna), and is tuned to a different frequency channel. If we imagine that these tuners are attached to power meters rather than speakers, we can watch the meters to continually monitor the power in each frequency channel. Now, if these power meters are connected to a computer which records the measurements, we have the basic workings of an analog filterbank. Note that this is different from the operation of most spectrum analysers, which sweep through the spectrum and measure the power in only one channel at a time; the analogy here would be to a single radio tuner which slowly sweeps across the bandwidth.

An alternative signal processing approach is coherent dedispersion. This technique completely removes the linear transfer function imposed by the dispersive ISM, and eliminates all dispersive smearing from the pulse profile. Coherent dedispersion can be thought of as a filterbank with an arbitrarily large number of arbitrarily narrow channels.

Analog filterbanks

Analog filterbanks are probably the easiest class to understand. We will use a highly simplified four-channel filterbank, depicted schematically in figure 2, to illustrate the operation of this type of instrument. The filterbank's input signal comes from the telescope feed; note that this signal is often mixed down (shifted to a lower frequency) from the frequency observed on the sky to simplify signal transmission and processing. An illustrative input spectrum (power per unit bandwidth as a function of frequency) is depicted in column (i) of the figure. This telescope feed signal is split four ways and passed directly to the input of each channel. From this point forward the signal is divided into four parallel channels, each processing a different part of the input spectrum. The input spectrum is filtered to select a smaller bandwidth for processing. Common filter types include LC and crystal filters, depending on the required passband characteristics. Columns (ii) and (iii) of the figure show the passband (transmission as a function of frequency) of each filter as well as the spectrum of the filtered signal, which is the multiplicative product of the input spectrum and the filter passband. At this point, we have simply divided the input spectrum up into several smaller sections. Next, in column (iv), the power in each channel is measured with a square-law detector. This detection is usually accomplished by passing the signal through a diode which is biased so that the output current is proportional to the square of its input voltage. This means that the current in the circuit at this point is proportional to the squared electric field of the signal received by the telescope, which is in turn proportional to the intensity of the observed source. This post-detection current is then integrated over an appropriate time interval with a simple RC circuit, analog-to-digital (A/D) converted to produce digital data, and finally sent to a computer for analysis. These data are proportional to the intensity of the source in the channel's passband integrated over the sampling time interval.

In order to receive all of the signal from a pulsar, both polarizations (either linear or circular) must be processed by the filterbank. This requires that all the steps described above prior to square-law detection be performed separately on each polarization. If polarization information is not required, the post-detection intensity signals can be combined to produce one data stream per frequency channel.

An example of an analog filterbank is the Penn State Pulsar Machine (PSPM), which is used at the 305 m radio telescope at Arecibo, Puerto Rico. This filterbank divides its 8 MHz bandwidth into 128 frequency channels and can measure the power in each channel as often as every 12 μs. This instrument is used for searching for new pulsars as well as timing known pulsars.

The number of channels in an analog filterbank can be effectively increased through the technique of Time Multiplexed Frequency Expansion (TMFE), as depicted in figure 3. Say we want to double the number of channels

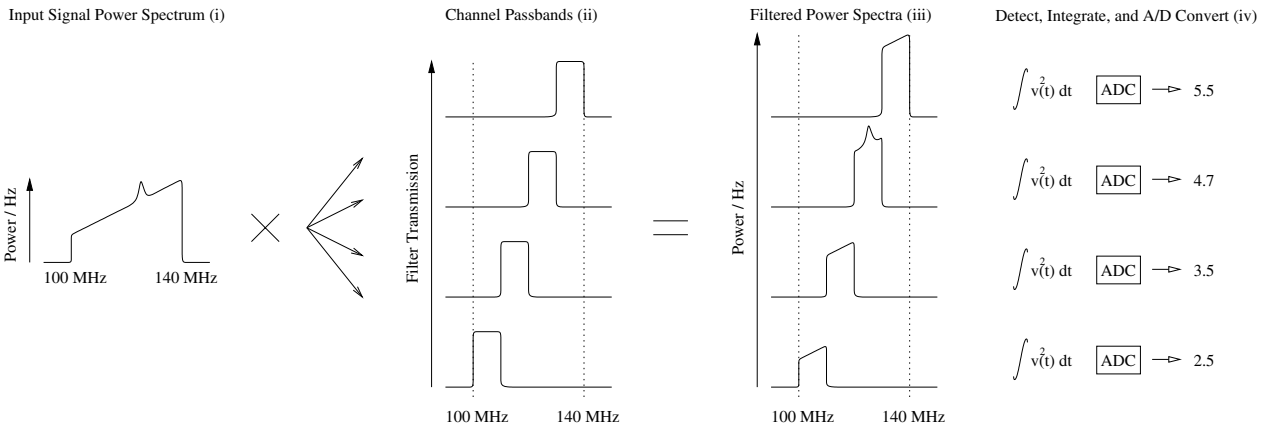

Figure 2. Analog filterbank schematic. The input spectrum is filtered, detected, integrated and A/D converted. See text for a detailed explanation.

in the filterbank in figure 2. Using TMFE, the input signal is first filtered into two channels, then each channel is digitized at baseband. The digitized data from both channels are stored in two sections of a single buffer; when this buffer is full the data are stored in a second buffer. At this point, a digital-to-analog (D/A) converter plays back the data from the low-frequency section of the first buffer, but at twice the original sample rate. This expands the bandwidth to 40 MHz—twice the original bandwidth of the channel, or the entire bandwidth of both channels. After mixing this signal up from baseband to the proper frequency for the filterbank input, the signal is fed into the filterbank. During this time, the four output channels of the filterbank contain data from only the lower half of the input bandwidth; thus we have now divided half of the bandwidth into four channels. These data are recorded for later analysis. Next, we follow the same playback procedure for the high-frequency section of the first buffer, and the filterbank divides this half of the bandwidth into four channels as well. So the output of the filterbank alternates, in this example, between four channels from an input passband of 100–120 MHz and four channels from an input passband of 120–140 MHz. Our effective channel bandwidths are now 5 MHz, as opposed to the 10 MHz of the original filterbank without TMFE. Since the TMFE system plays back its data at twice the sample rate, both sections of the first buffer can be replayed in the time it takes to fill the second buffer, so there is no loss of observing efficiency. The data in the second buffer are now fed into the filterbank while the first buffer is filled with new data, and the process repeats. It is easy to see that we can increase the effective number of filterbank channels by a factor of N by using N TMFE filters, A/D converters and buffer subdivisions, and by running the D/A converters at N times the sample rate. A TMFE system with $N = 4$ is in operation at the Parkes 64 m telescope in Australia, in conjunction with a pre-existing analog filterbank.

Digital filterbanks

The steps taken inside a digital filterbank are similar to those in the analog filterbank, but they are accomplished through different electronic means. In a digital filterbank, the input voltage signal from the telescope is sampled and digitized. This digitized signal is then subdivided into channels by digital filters, for instance finite impulse response (FIR) or infinite impulse response (IIR) filters. As an example, in the FIR case, the filter is programmed with coefficients of the discrete Fourier transform of the desired filter passband. The output of the filter for a given input data stream is then the convolution of a series of contiguous input data with the filter coefficients. This appears very different from the analog filtration process, but the Convolution Theorem guarantees that the result will be the same. As the filtered signals are already digital numbers, 'square-law detection' is accomplished by simply squaring the data, and integration by simply summing the desired number of samples.

The Navy–Berkeley Pulsar Processor (NBPP) is a digital filterbank used at the Nançay Observatory in France. This instrument has 96 channels; its FIR filters can be programmed to cover a total bandwidth of up to 168 MHz. It is designed to search for pulsars at observing frequencies above 1 GHz.

Digital filters can also be used to accomplish coherent dedispersion, as in the Green Bank–Berkeley Pulsar Processor (GBPP), at the National Radio Astronomy Observatory in Green Bank, West Virginia. After the digital bandpass filtering described above, this instrument uses a series of high-performance FIR devices to counteract the dispersion in each channel. These custom-designed PULFIR chips convolve the data stream with up to 1024 coefficients, which correspond to the dispersive transfer function for a given DM.

Fast Fourier transform filterbanks

Another way of producing what is effectively a filterbank involves no filters at all, but rather uses integrated

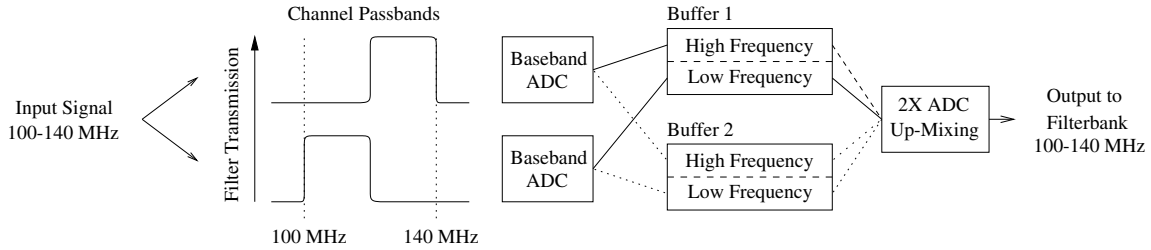

Figure 3. TMFE schematic. The signal is filtered, digitized, buffered and D/A converted sequentially at, in this example, twice the sample frequency. See text for a detailed explanation.

circuits optimized for performing fast Fourier transforms on digitized signals. As with the digital filterbank, the telescope signal is first digitized. However, rather than sending the digitized signal through a series of filters, one per channel, it is fed into an FFT chip. This dedicated computer calculates the discrete Fourier transform of a segment of the data stream, which is the discrete amplitude spectrum of the signal. To obtain the power spectrum of the signal, we need only to square the amplitude spectrum, multiplying by its complex conjugate. As this discrete power spectrum is nothing more than the power contained in individual frequency channels, we have effectively created a filterbank. These data can now be integrated by summing the output over a desired number of cycles, as with the digital filterbank.

Since we can only calculate the FFT of a short segment of data at one time, the Fourier transform we compute will be the convolution of that intrinsic to our input signal and that of the window function which is applied to it. In the simplest case, this window function is unity for the samples that make up the short input data segment and zero for all earlier and later times. This simple window function has as its Fourier transform a sinc function. When convolved with the transform of the signal, the result is that a significant amount of the amplitude, and hence power, of each component of our intrinsic spectrum is lost in the sidelobes of this sinc function. We can minimize this loss of power into spectral sidelobes by Hanning smoothing the input data. This involves multiplying the input data set by a window function which tapers to zero at the ends. The Fourier transform of this window function has a broader main peak, but much smaller sidelobes, than in the previous case. This decreases our spectral resolution slightly, but the power scattered into the sidelobes is greatly reduced; the result is a much cleaner power spectrum. With Hanning smoothing, the data near the ends of our input segment are weighted much less heavily than those near the center of the segment. To compensate for this loss, the input segments are commonly overlapped, meaning that only perhaps half of the input segment is replaced for each new FFT.

An example of an FFT filterbank is the Arecibo Observatory Fourier Transform Machine (AOFTM), which synthesizes 1024 channels covering a 10 MHz bandwidth and has 102 μs time resolution.

Software filterbanks

One final way of creating a filterbank is to simulate one using computer software. In this system, the signal from the telescope is Nyquist sampled (with a sample frequency of at least $2B$), digitized and recorded for later analysis. This method is the most computationally intensive and generates huge amounts of data, but the hardware is relatively simple and all of the information in the telescope signal is preserved. The data are later processed by a general purpose computer, which can be programmed to perform coherent dedispersion, or to simulate a digital filterbank with FIR or IIR filters, or an FFT machine. Software filterbanks will become more and more practical as computing power increases; at present they are limited to relatively small bandwidths compared with the other types of filterbanks. The computing power required to process each megahertz of bandwidth in real time is about 50 million floating point operations per second (MFlops) for a simulated incoherent filterbank and 200 MFlops for coherent dedispersion.

An example of this kind of instrument is the Caltech Baseband Recorder (CBR), used at Arecibo Observatory. This instrument covers a 10 MHz bandwidth, taking data at a rate of 20 MB s^{-1}. The data are analysed off-line using supercomputers.

Filters

Filters are used in astronomy for two main purposes, to either lower the overall intensity of the light or to restrict the wavelength range of the light that is being measured. When the eye was the only astronomical detector, filters were scarcely used, but astronomy has always adopted the new technologies of the day, be it photography, photomultiplier tubes, image tubes, CCDs or IR arrays. As the new detectors invariably have a wider wavelength response and/or improved sensitivity than previous detectors, filters became very important in order to match previously used bandpasses and to sample the flux of astronomical sources at different wavelengths thus providing some astrophysical information on the source's temperature and other properties. Some filters work by selective absorption and transmittance: these are the colored glass filters. Others work by selective reflection and transmittance: these are usually referred to as interference filters.

An interference filter comprises a multi-layer of thin films that selectively transmits or reflects light of particular wavelengths. They fall into two broad types, bandpass filters (usually narrow bands) and edge filters, that transmit above or below a certain wavelength; dichroic beamsplitters are edge filters. The Fabry–Perot tunable filter is a unique interference filter that can be used to spectacular effect on emission-line objects (see also TUNABLE IMAGING FILTERS). Finally, there are filters used for measuring polarized light and studying astronomical magnetic phenomena.

Colored glass filters

The first filters used in astronomy were colored glass (Schott or Corning) or colored gelatin (Kodak). These were used with photographic emulsions to define B, V, R and I bands. Colored glasses had been made for thousand of years for expensive glass vessels and ornaments. Nowadays, colored glasses are produced in one of two ways, either by ionic coloration or by absorption and scattering from a suspension of colloidal particles that are produced in the glass and controlled in size by heat treatment after an essentially colorless glass is made. Figure 1 shows some sample transmittance curves of these glass filters.

The ionic glasses are made by dissolving particular salts (such as cobalt or nickel oxide) in glass. The ionic coloration of the UG (violet) and BG (blue) series of glasses produces a spectral transmittance curve resembling a bell-curve of half-width between 100 and 200 nm but most of these glasses also transmit red light beyond 700 nm as well, thus the violet glasses appear purple to the eye.

The second type of colored filter glass are a series of sharp edge (or short-wave cut-off) filters, the WG, GG (sulphur and cadmium sulfide), OG (cadmium selenide) and RG (gold) series which absorb light blueward of a quite sharply defined wavelength. The filters are made with their short-wave cut-offs ranging from 400 to 800 nm in steps of 20 nm. To the eye, the WG glasses are essentially colorless, the GG series go from colorless through light yellow to dark yellow, the OG are orange-red and the RG series are rose to ruby in color.

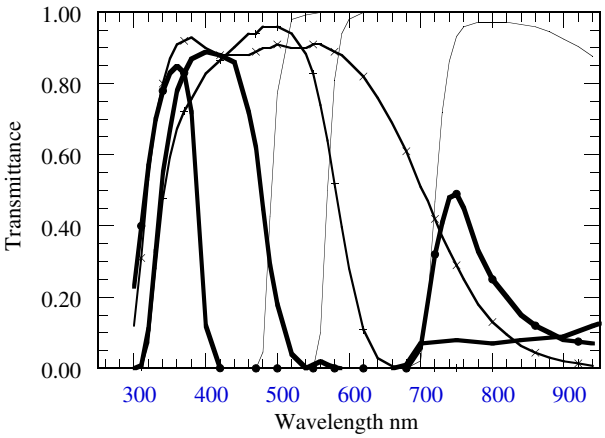

Figure 1. The transmittances of a sample of colored glass filters. The thick curves are for the ionic colored glasses UG1 (dots) and BG12. The medium thick curves with symbols are S8612 and KG3 used as red cut-off glasses. The thin curves are three of the family of short-wave cut-off glasses GG495, OG570 and RG9.

Schott also make two special (nearly) colorless glasses (BG39/40 and the KG series) that can be used as long-wave cut-off filters; however, these glasses have long-wave cut-offs that fall more slowly (over about 250 nm) than the short-wave cut-offs rise (over about 50 nm) thus producing an asymmetrical spectral transmittance curve when used together to define a bandpass. Where a steeper cut-off is desirable, it is necessary to use an edge interference coating (see below) in combination with a Schott short-wave cut-off filter. An important use for the BG39/40 and S8612 glasses is also as a 'red-leak' blocker, absorbing light beyond 700 nm where most of the Schott blue and violet glasses transmit. Polished copper sulfate crystals or a copper sulfate solution have also been used in astronomy as a UV transmitting blue filter to block red leaks, but the improved UV transmission of S8612 glass, although not as high as that of copper sulfate, has enabled it to replace copper sulfate for most imaging applications.

Combination filters and bandpasses

The ionic colored glasses define broad bell-shaped bandpasses in the violet, blue or green regions; however, the choice is restricted. Better definition has traditionally been obtained by combining one of those filters with one of the long-pass glass filters, or by using a long-pass glass filter and the red sensitivity cut-off of the detector, for instance the particular sensitization of a photographic emulsion (O, G, D, E, J, F, N) or the fall-off in the sensitivity of a photocathode (S5, S11, S20, GaAs). But with the use of wide wavelength response CCD detectors and the restriction of photographic emulsions to the broad band Tek Pan film, it is now necessary to have filter defined

bandpasses. This is also true in the IR and the UV, where in the past, the atmospheric windows were often partly used to define the edges of the bandpass resulting in the bandpass differing between seasons and with observing altitude. The standard U, B, V and R bandpasses can be defined using only glass filters but better R and I bandpasses can be made using interference edge filters for the red cut-offs. The bandpass filters for the SLOAN DIGITAL SKY SURVEY have been defined in this fashion, the short-wave cut-off coming from the Schott color filter and the long-wave cut-off from an interference edge filter. It is necessary to use BG39 with other BG glasses and S8612 with UG glasses to eliminate the red leak of those glasses.

Combination glass filters have been used successfully with CCD systems to match the standard UBVRI system (see MAGNITUDE SCALES AND PHOTOMETRIC SYSTEMS). The thicknesses of the glasses can be adjusted to tune the passband for better results with detectors having different wavelength responses.

Practical consideration

From a practical viewpoint, many of the BG and all the UG glasses are difficult to use. They are hard to polish, tarnish in air easily and the high concentration of ions in the available glasses often means that they are brittle and the required blue or violet color is produced with only a thin piece (1 mm or less) of the glass. This is unfortunate, as it means that it is difficult to produce good optical quality glass sandwiches in a large enough size to cover the focal plane of the large SCHMIDT TELESCOPES where it is desirable to have such a blue and ultraviolet filter for use with the new Tek Pan film. However, up to 25 cm square filters suitable for CCD arrays can readily be made. Large glass pieces are usually unavailable from stock and if ordered have to await a new melt. Some glasses, e.g. UG2 and BG37, are no longer made.

Neutral density filters

Although astronomical objects are generally very faint, it is sometimes necessary to attenuate light. The NG series of Schott filters provides a large range of attenuation and are especially useful when it is better to absorb the light rather than reflect it away. However, the attenuation is not especially constant with wavelength and the glasses absorb shortward of 400 nm. For astronomical objects therefore it is usually preferable to use filters made from fused silica that have been coated with a metallic alloy. This provides excellent attenuation that, although not identical for all wavelengths, is usually close enough to be easily calibrated. These coated fused silica filters can be used from the UV to 2 μm. For IR wavelengths germanium substrates are used. These filters are also made with a wedge or radial gradient of attenuation that is useful in non-quantitative situations.

Interference filters

Thin film coating technology has matured, and excellent interference filters are available from many manufacturers using computer designed coatings and computer controlled coating plants.

Bandpass filters

Bandpass interference filters are made by coating a glass or fused silica substrate with alternating layers of $\lambda/4$ reflective and $\lambda/2$ transmitting dielectric materials to make a single or multiple Fabry–Perot interferometer. The spacings between the layers is designed to enhance the transmittance at the wavelength of interest. By varying the reflectivities, the number of layers and the number of Fabry–Perot cavities the shape and width of the bandpass can be altered.

The more cavities, the squarer the bandpass is. Square bandpasses are desirable for emission line photometry so that the response is uniform across the field (changing angle) and for a range of RADIAL VELOCITIES. But for some astronomical purposes, such as broad band continuum photometry, square bandpasses are not desirable as they produce too great a response difference as a particular spectral feature moves in and out of the band due to radial velocity differences or chemical and physical differences between objects. Similarly, square bandpasses can also result in big differences when a filter is replaced by another whose bandpass is not precisely the same. For that reason, combination glass filters, or glass and interference edge filters, have been preferred for continuum photometry. However, rapid advances in coating technology, including rugate filter technology, now enable arbitrary shaped bandpasses with high throughput to be made. It is likely that interference filters in the future will increasingly replace most colored glass filters.

Interference filters are produced as a glass sandwich, usually between two colored blocking glasses. Because of the hygroscopic nature of the coatings the edges are sealed with epoxy and encased in an aluminum cylinder. The filters are normally between 5 and 10 mm thick depending on the diameter and the manufacturer.

Shifts in bandpass

The bandpass of an interference filter shifts blueward as the incident angle deviates from the normal. This can be useful as it enables a blueward tuning of the filter to be done. Typically a 5 degree tilt shifts the central wavelength of a 656 nm filter by about 0.7 nm while a 10 degree tilt shifts it by 2.7 nm. As most imaging is done with a converging beam the bandpass will broaden and shift blueward depending on the f/ratio of the telescope and position in the field. It is necessary to take this into account when designing narrow band imaging filters.

Temperature will also shift the bandpass as the distance between the layers changes. Typical optical interference filters at room temperatures show shifts of about 0.003% of the peak wavelength per °C. This is about 10 times less than a typical glass edge filter, such as GG395 or OG590.

Edge filters

Unlike bandpass filters, edge filters do not contain cavities. Generally they consist of quarter-wave and modified quarter-wave layers that produce an 'edge' in wavelength

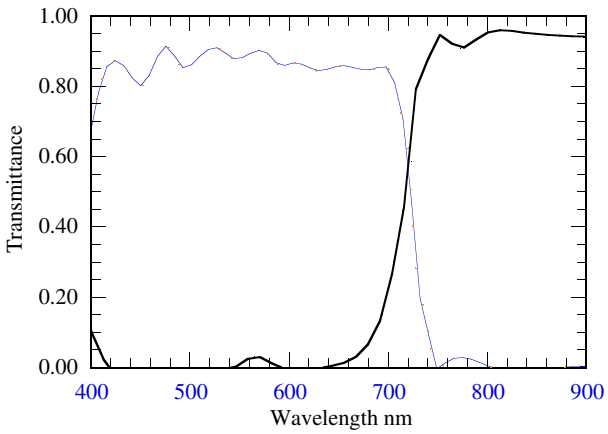

Figure 2. The transmittances of typical multilayer (interference) edge filters. The thin curve is for the short-pass filter used for defining the red edge of a passband or as a heat reflecting dichroic filter. The thicker line is for a long-pass filter that could be used as a dichroic beamsplitter in a spectrograph, reflecting blue light and transmitting red light.

space as the filter changes from reflection to transmission. Figure 2 shows examples of typical short-pass and long-pass filters. Short-pass edge filters are often used with long-pass glass filters to define astronomical photometric bandpasses. *Dichroic mirrors* are edge filters used at an angle of 45°. In optical spectroscopy they are normally used to reflect light blueward of some limit into one spectrograph and transmit the remainder into another. They are often also used to reflect IR light to an IR instrument and transmit the optical light to a guider.

Fabry–Perot tunable filters

A Fabry–Perot interferometer has been introduced at two observatories that has revolutionized the way in which high-efficiency intermediate to narrowband imaging can be carried out. Advances in coating techniques, precise spacing control of the interferometer plates and an innovative charge shuffling technique on the CCD detector have made this possible. More details can be found at (http://www.aao.gov.au/local/www/jbh/ttf/). The filter can be tuned between 370 and 1000 nm and the resolution chosen between 100 and 1000. At low resolutions (below 300), normal broad band BVRI filters can be used to block sidebands. At high resolution (1000) a set of intermediate interference filters are needed for sideband suppression. Unprecedented observations have been made with this new instrument.

Rugate filters

A rugate filter is an interference coating in which the refractive index of the coating varies continuously through its thickness. This provides greatly enhanced flexibility in filter design and extremely high levels of rejection. Multiple passbands can be produced, for instance to transmit two emission lines of interest, or to reject certain wavelengths, such as the strongest night sky emission lines or intense laser lines for safety goggles.

Antireflection coatings

Typical glass surfaces reflect about 4% of the normally incident visible and near-IR light. Silicon and germanium reflect over 60%. To avoid light loss and problems associated with reflected stray light from bright stars and the sky, antireflection coatings are usually applied to all optics including the filters. Multilayer coatings can be designed to produce extremely low reflectivities over a wide wavelength range, but for filters, a single-layer coating designed for the central wavelength of the filter is usually adequate. The most effective single layer is a $\lambda/4$ thickness of material whose refractive index is the square root of that of the glass.

Finder

A small telescope of low magnification and relatively wide field of view that is attached to the main telescope and can be adjusted to be exactly parallel to the optical axis of the main instrument. Because its field of view is wider than that of the main telescope, it is much easier for the observer to locate the object of interest in the finder (provided it is bright enough to be seen or near something bright enough to be seen) than in the narrow field of the main instrument. Once the object has been identified, the telescope controls are adjusted to bring it to the center of the field of view of the finder (which may be marked by crosswires). It should then be readily visible within the field of view of the main telescope.

Modern telescopes that are computer controlled can position themselves on a celestial object to arc-second accuracy and have little need for a finder telescope.

Fireball

An exceptionally bright meteor, traditionally defined as one that exceeds the planets in brightness. Since Venus at greatest brilliancy reaches magnitude -4.7, a fireball is now generally taken to be a meteor with a magnitude of -5 or greater. About one meteor in every thousand recorded is a fireball. Some meteor showers, for example the Geminids, are particularly productive of fireballs. Among sporadic meteors, fireballs are most likely to occur in the spring. Fireballs are produced by larger than average meteoroids and are usually of asteroidal rather than cometary origin, and therefore denser. A sufficiently large object will not only produce a fireball but will be only partially consumed by its passage through the Earth's atmosphere, and will fall to the surface as a meteorite. A fireball that generates a sonic boom is known as a bolide.

Fission

The breaking apart of a body into smaller fragments. In the context of nuclear physics the term, nuclear fission, refers to the splitting of a heavy atomic nucleus into two or more lighter nuclei with the release of energy. The mass of the nucleus prior to fission is greater than the combined masses of the fragments, the difference in mass, Δm, being released as a quantity of energy, ΔE ($\Delta E = \Delta m c^2$, where c denotes the speed of light).

For example, the capture of a neutron by a uranium-235 nucleus causes that nucleus to break into two fragments (a nucleus of molybdenum-98 and a nucleus of xenon-136), together with two neutrons and a substantial quantity of energy (212 MeV). Because the reaction liberates additional neutrons, a chain reaction is possible in a mass of uranium. If the reaction is allowed to build up, unchecked, a nuclear explosion will take place (this is the basis of the atomic bomb), while if the rate of the reaction is controlled, by regulating the supply of neutrons, a steady output of energy can be achieved (this is the basis of the nuclear reactor).

Fitzgerald [FitzGerald], George Francis (1851–1901)

Irish physicist, born in Kill-o'-the Grange, Monkstown, Co. Dublin, became professor at Trinity College Dublin, identified the reason for the result of the Michelson–Morley experiment, as the shrinkage of a body due to motion at speeds close to that of light. LORENTZ independently came to the same conclusion, and the effect is called the *FitzGerald–Lorentz contraction of relativity*.

Five College Radio Astronomy Observatory

The Five College Radio Astronomy Observatory (FCRAO) is a research organization within the University of Massachusetts which aims to conduct astronomical research, to develop state of the art microwave instrumentation, and to train both graduate and undergraduate students with support from the National Science Foundation and the Commonwealth of Massachusetts.

FCRAO operates the 14 m telescope located in New Salem, Massachusetts for observations within the 3 mm wavelength band. Recent instrumentation highlights include the development of large format focal plane array receivers. FCRAO students, scientists and visiting observers have exploited the capabilities of the system to conduct unique, wide field imaging studies of the molecular interstellar medium in the Milky Way, detailed studies of star forming regions and the molecular gas content in external galaxies.

FCRAO is a partner with the Instituto Nacional de Astrofisica, Optica y Electronica (INAOE) in Mexico to construct the Large Millimeter Telescope, a 50 m antenna on Cerro La Negra. This facility will be capable of efficient operations between 85 and 345 GHz to explore the early epoch of galaxy formation, the structure of nearby galaxies, and the physical and chemical processes within the molecular interstellar medium.

Fizeau, Armand (1819–96)

French physicist, first measured the speed of light by reflecting it over an 8 km distance through a rapidly rotating toothed disk known as the *Fizeau wheel*, which was used to measure the time of flight over that distance. Suggested using a twin-aperture interferometer to measure stellar diameters, calculating that interference fringes would vanish at a separation related to the size of the star's disc. Idea followed successfully by MICHELSON.

Flagstaff Field Center

The US Geological Survey Flagstaff Field Center was established in 1963 to provide geologic information about the Moon and to help train astronauts. After Apollo, research expanded to support robotic exploration of the planets and the study of climate and human impacts on the natural environment. Future research (terrestrial and extraterrestrial) will reflect the increasingly global nature of society's needs, quests and problems.

Flame Nebula (NGC 2024)

A bright nebula in the constellation Orion, position RA $05^{\mathrm{h}}\,41.9^{\mathrm{m}}$, dec. $-01^{\circ}\,51'$. About $\frac{1}{2}^{\circ}$ across, its illuminating source is hidden behind a patch of dark nebulosity that crosses its center.

Flammarion, Nicolas Camille (1842–1925)

French astronomer and geophysicist, born in Montigny-le-Roy, observed double stars, and planets from his observatory at Juvisy, south of Paris. Very well-known for his popularization of astronomy, including many lavishly illustrated books (for example *L'Astronomie Populaire*) and a journal *L'Astronomie*, still published. It was Flammarion who, as shown by Arthur Beer and Bruno Weber, drew, sometime before 1888, a much reproduced 'German medieval woodcut' showing the Ptolemaic uinverse with a pilgrim looking through a celestial sphere to the mechanism beyond.

Flamsteed, John (1646–1719)

Born in Denby, Derbyshire, England, the first Astronomer Royal, a term then synonymous with director of the Royal Observatory, Greenwich, whose creation he had proposed directly to King Charles II. The observatory was completed in 1675, and the King appointed Flamsteed at a salary from which he had to provide his own instruments. Flamsteed was a skilled observer, making the most accurate measurements of the positions of the stars and Moon then known, for the purpose of navigation (particularly for determining longitude). He was a perfectionist and when SIR ISAAC NEWTON, on the Board of Visitors (governors) of the observatory, pressed Flamsteed to release preliminary data on the Moon, to test the law of gravitation, they clashed. HALLEY intervened on behalf of Newton and edited the observations for immediate publication, over Flamsteed's objections. Flamsteed bought and burned 300 of the edition of 400, and the book is very rare. Flamsteed left his definitive observations to be published by his widow as *Historia Coelestis Britannica*. He introduced a system of letters and numerals for stars, in sequence by right ascension within a constellation, and known as *Flamsteed numbers*, e.g. 61 Cygni.

Flare

A localized explosive release of energy, usually from a site located within a complex solar active region, in which up to 10^{25} J can be liberated within a few thousand seconds. A typical flare reaches peak brightness within the first 5 min of the event and declines more slowly over the next 20 min. Some flares can last for up to three hours.

Flares emit radiation over practically the entire electromagnetic spectrum from hard (short-wavelength) x-rays, or even gamma rays, to radio waves, the bulk of the energy being emitted at x- and extreme ultraviolet wavelengths. They eject streams of high-energy subatomic particles, including electrons (which in some cases are accelerated to speeds in excess of half the velocity of light), protons and small numbers of heavier nuclei, and expel bulk clouds of plasma through the corona into interplanetary space. As the high-speed particle streams and plasma clouds plow through the corona, they stimulate the emission of microwave and radio radiation across a wide range of frequencies. These dramatic events also send shock waves across the surface of the Sun and into its interior and trigger various kinds of prominence phenomena.

Flares are believed to be caused by the sudden release of magnetic energy that had previously been stored in the twisted magnetic fields of complex sunspot groups or active regions by means of a process called magnetic reconnection. This occurs when oppositely directed field lines come into contact, sever, and join up to form new field structures—for example a closed loop with its 'feet' connected to the solar surface and an open U-shaped structure above. In the process, part of the energy contained in the magnetic field is converted into other forms of energy, such as thermal (heat) energy and the kinetic energy of particle streams. Localized heating at the site of the reconnection produces much of the soft (longer wavelength) x-ray and extreme ultraviolet radiation, while electrons accelerated down the loops produce bursts of hard x-rays and hydrogen-α (optical) radiation where they plow into the chromosphere. Hard x-rays are also produced above the site of the flare by shock waves that heat the coronal plasma to temperatures of around 2×10^8 K. Like an elastic string, a magnetic field line has tension in it. Consequently, when a magnetic field structure severs and reconnects, it catapults bulk plasma outwards.

Flares have a variety of effects on the Earth. High-speed particles from solar flares take about 30 min to travel to the Earth. Low-energy particles and disturbances produced in the solar wind by the flare take from a few hours to a couple of days to arrive. Charged particles plunging into the upper atmosphere give rise to auroral displays. Flare-generated x-ray and ultraviolet radiation disturbs the Earth's ionosphere and can therefore disrupt terrestrial radio communications. Clouds of ejected plasma, and disturbances in the solar wind and interplanetary magnetic field, squeeze and stretch the Earth's magnetosphere, giving rise to magnetic storms and surges in power transmission lines.

Flash Spectrum

The emission-line spectrum of the solar chromosphere. The name derives from the fact that when the Sun is observed with the aid of a spectroscope, during a total solar eclipse, the faint chromospheric emission lines suddenly flash into view at the instant when the much more brilliant light of the photosphere is blotted out completely by the disk of the Moon. American astronomer Charles Young first observed the flash spectrum in 1870.

The visible spectrum of the chromosphere consists of a very weak continuum on which are superimposed thousands of emission lines. When the solar disk is viewed directly, these faint emission lines cannot be seen against the intensely luminous photosphere. Instead what is seen is the continuous spectrum of the photosphere together with the superimposed pattern of dark absorption lines that results from absorption of light as it moves out through the photosphere and chromosphere. When, as at a total eclipse, chromospheric gas can be seen at the limb (the edge of the solar disk) without the background photospheric light, the emission lines show up clearly. Because different lines become prominent at different temperatures, observations of the chromospheric spectrum made at different heights above the limb yield information about how the temperature of the solar atmosphere varies with altitude. During a total solar eclipse, the appearance of the flash spectrum changes rapidly as the Moon's disk advances across the thin chromospheric layer at the solar limb, and therefore allows observers to receive light from different altitudes above the solar surface.

Fleming, Williamina Paton Stevens (1857–1911)

Astronomer, born in Dundee, Scotland, emigrated to Boston with her parents and worked as a maid in the home of EDWARD PICKERING, the director of the Harvard Observatory. Unhappy with the work performed by his existing employees and declaring that his maid could do a better job, Pickering hired her for clerical work and mathematical calculations. Fleming devised a system of classifying stars according to their spectra, obtained by Pickering from images of the stars obtained by photographing the sky through a prism placed over a wide-field camera. This resulted in a catalog of the 'spectral types' of 10 000 stars, published in 1890 as the first *Draper Catalog of Stellar Spectra* and the basis of the several volumes (1918–24) of the definitive *Henry Draper Catalog* drawn up by ANNIE CANNON. Discovered 222 variable stars and 10 novae.

Fluid Dynamics

Fluid dynamics is a subfield of continuum mechanics which deals with the theory of motion of a fluid (hydrodynamics) or gas (gas dynamics).

Fluid dynamics is studied theoretically, experimentally and by means of numerical simulations. The phenomena of fluid motion are governed by well known continuum laws of physics: the conservation of mass, momentum and energy. Whether these continuum laws accurately describe a given physical system depends both on the mechanical and thermodynamic state of the system (i.e. its density, temperature, etc) and on the kind and strength of the interaction of its constituents (e.g. the scattering rate of gas particles). The matter of astrophysical objects (e.g. of a star or galaxy) can often be approximated as a gas or fluid, i.e. the equations of fluid dynamics are adequate to describe the astrophysical phenomena. Hereafter, for simplification, the word fluid will be used as a synonym for both fluid and gas.

The conservation laws describing the motion of a fluid can be formulated as set of nonlinear partial differential equations. Analytic solutions of this set of equations only exist for simplified highly symmetric flow problems, and the mathematical theory is often difficult. For this reason, observations of fluid motion in nature, in the laboratory and with computers are also essential for understanding the motion and behavior of fluids.

In astrophysics the numerical tool is often the only one available to the researcher. Moreover, as most astrophysical conditions are inaccessible in the laboratory, and as astrophysical fluid motion may occur on time scales long compared with the lifespan of humans or deep inside astrophysical objects, numerical simulation is the only means to study such fluid motion. The study of astrophysical fluid flows is further complicated by the effects of self-gravity, which must be considered in many astrophysical flow problems, by the enormous range of length scales and time scales to be covered in the simulations, and by a variety of other physical effects which must be taken into account frequently. The latter include radiation transport (of photons and neutrinos), heat conduction, radiative cooling, ionization and recombination of atoms, magnetic fields, energy generation by thermonuclear reactions, flow velocities near the speed of light and in strong gravitational fields, and the properties of dense matter.

Applicability of fluid dynamics

Two requirements must be fulfilled in order for the continuum approximation of fluid dynamics to hold.

Firstly, one has to assume that the microscopic behavior of single particles can be neglected. This requires that $\lambda \ll L$, where λ is the collisional mean free path of the particles and L is a characteristic macroscopic linear dimension of the system, or a scale over which the distribution function varies significantly. If the above equation holds, the concept of a fluid element can be introduced, the linear size of the fluid element being small compared with L but large compared with λ. This implies that the number of particles in the fluid element is large, and hence mean physical quantities, like, for example, the fluid density ρ or the fluid velocity $\boldsymbol{v}$ can be defined for the fluid element. The velocity of the individual particles is then given by $\boldsymbol{u} = \boldsymbol{v} + \boldsymbol{w}$, i.e. it possesses a random component $\boldsymbol{w}$ above the mean. Because $\lambda \ll L$, however, the particles only perform a random walk about the mean motion $\boldsymbol{v}$, and consequently the fluid element remains well defined during the evolution except for some small loss of particles near its surface, which, if necessary, can be well described by an additional diffusion term in the hydrodynamic equations.

Secondly, the forces between particles must be saturating or 'short range', because otherwise collective effects must be taken into account. Formally this can be expressed by the requirement that the energy per particle E/N must approach some constant value when the number of particles tends to infinity. For a fluid element with volume V one can then define an energy density $\varepsilon \equiv E/V = n(E/N)$ where $n \equiv N/V$ is the number density, and a pressure $p = n(\partial\varepsilon/\partial n) - \varepsilon$ exerted on the 'walls' confining the fluid element. Examples of non-saturating forces are gravity and electromagnetic forces which both scale as $(\sim r^{-2})$. Consequently, gravity must be included in the hydrodynamic equations as a macroscopic external force. Although electromagnetic forces are long range too, they saturate in electrically neutral systems due to screening.

Equations of fluid dynamics

The equations of fluid dynamics can be derived by a phenomenological approach or within the framework of the KINETIC THEORY. In the phenomenological approach one postulates certain relations between stress and rate of strain and between heat flux and temperature gradient and develops the fluid dynamic equations from the universal laws of conservation of mass, momentum and energy. The required constants of proportionality between stress and rate of strain and between heat flux and temperature gradient are called transport coefficients and must be determined experimentally.

The equation that results from requiring the conservation of mass in a fluid flow is called the *continuity equation*. The conservation of momentum law or Newton's second law applied to a fluid yields a vector equation known as the *Navier–Stokes equation*. The First Law of Thermodynamics or the conservation of energy law imply a fluid dynamic equation which is called the *energy equation*.

In the kinetic theory approach the fluid dynamic equations are derived from the *Liouville equation* by defining the transport coefficients in term of certain integral relations which involve the dynamics of colliding particles. The drawback to this approach is that the interparticle forces must be specified in order to evaluate the collision integrals. Both the phenomenological approach and the kinetic theory approach yield the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

same fluid dynamic equations provided equivalent assumptions are made during their derivations.

Mathematically speaking the five fluid dynamic equations form a set of coupled nonlinear partial differential equations which are of first order in time and of second order in space. They describe the evolution of mass density ρ, momentum density $\rho\boldsymbol{v}$ and (total) energy density e in time and space. In addition to the evolution equations, it is necessary to supply a relationship between fluid properties in order to close the system of equations. The equation of state is an example of such a relationship. It relates the thermodynamic variables pressure p, density ρ and temperature T or internal energy density ε.

In many astrophysical applications of fluid dynamics, additional equations and/or additional source terms have to be considered, which for example describe composition changes and energy generation due to nuclear reactions, the diffusive transport of matter or radiation (diffusion equation), magnetic fields and their coupling to matter (magnetohydrodynamics), the evolution of radiation fields and their interaction with matter (radiation hydrodynamics), and self-gravity. Moreover, in certain applications the conservation equations have to be formulated consistently with SPECIAL or GENERAL RELATIVITY.

Form of the equations

Here the equations of fluid dynamics are given without derivation. The various quantities appearing in the equations below are defined as follows: $\boldsymbol{u} = \boldsymbol{v} + \boldsymbol{w}$ is the particle velocity, $\boldsymbol{v}$ the average fluid velocity, $\boldsymbol{w}$ the statistical fluctuation around the mean flow, ρ is the fluid density, $\rho\boldsymbol{v}$ is the fluid momentum, and $\rho\varepsilon$ (erg cm^{-3}) is the kinetic energy density about the mean motion (i.e. the internal energy), respectively.

The *continuity equation*

$$\frac{\partial\rho}{\partial t} + \mathrm{div}(\rho\boldsymbol{v}) = 0$$

describes the conservation of mass, the *Navier–Stokes equation* of motion

$$\frac{\partial}{\partial t}(\rho\boldsymbol{v}) + \mathrm{div}(\rho\boldsymbol{v}\otimes\boldsymbol{v}) + \mathrm{div}\underline{\underline{\Pi}} = -\rho\mathrm{grad}\Phi \qquad (1)$$

describes the transport of (relative) momentum in the flow. The total energy equation (assuming that the particles have no internal degrees of freedom)

$$\frac{\partial}{\partial t}\left(\frac{\rho}{2}|\boldsymbol{v}|^2 + \rho\varepsilon\right) + \mathrm{div}\left[\left(\frac{\rho}{2}|\boldsymbol{v}|^2 + \rho\varepsilon\right)\boldsymbol{v}\right] + \mathrm{div}\vec{h} + \mathrm{div}(\underline{\underline{\Pi}}\boldsymbol{v}) = -\rho\boldsymbol{v}\mathrm{grad}\Phi$$

finally describes the conservation of energy. $\underline{\underline{\Pi}} \equiv \rho\langle\boldsymbol{w}\otimes\boldsymbol{w}\rangle$ is the pressure tensor, from which one usually separates out the trace of the symmetric dyadic $\boldsymbol{w}\otimes\boldsymbol{w}$, i.e. one writes

$$\underline{\underline{\Pi}} = P\underline{\underline{I}} - \underline{\underline{\pi}}$$

where

$$P \equiv \tfrac{1}{3}\rho\langle|\boldsymbol{w}|^2\rangle$$

is the isotropic fluid (or gas) pressure

$$\underline{\underline{\pi}} \equiv \rho\langle\tfrac{1}{3}|\boldsymbol{w}|^2\underline{\underline{I}} - \boldsymbol{w}\otimes\boldsymbol{w}\rangle$$

is the viscous stress tensor and $\underline{\underline{I}}$ is the unit tensor.

$$\varepsilon \equiv \tfrac{1}{2}\langle|\boldsymbol{w}|^2\rangle$$

is the specific internal energy (erg g^{-1}), and

$$\vec{h} \equiv \rho\langle\boldsymbol{w}\tfrac{1}{2}|\boldsymbol{w}|^2\rangle$$

is the conduction heat flux. The operator $\langle\rangle$ denotes an average over the one-particle Boltzmann distribution function.

In the absence of viscosity the Navier-Stokes equation reduces to the *Euler equation*

$$\frac{\partial}{\partial t}(\rho\boldsymbol{v}) + \mathrm{div}(\rho\boldsymbol{v}\otimes\boldsymbol{v}) + \mathrm{grad}\,P = -\rho\mathrm{grad}\Phi.$$

For the special case of an *adiabatic flow* the total energy equation reduces to the simpler form

$$\frac{\partial e}{\partial t} + \mathrm{div}[(e+P)\boldsymbol{v}] = -\rho\boldsymbol{v}\mathrm{grad}\Phi$$

where $e = \frac{1}{2}\rho|\boldsymbol{v}|^2 + \rho\varepsilon$ is the total energy density (erg cm^{-3}).

Flow regimes

Fluid flows can be uniquely classified into different flow regimes depending on the value of certain characteristic dimensionless flow parameters. Different flows having the same dimensionless flow parameters are called similar.

Depending on the degree of compressibility of a fluid under forces acting on it, it can be treated as either being *incompressible* or *compressible*. In the former case the fluid dynamic equations can be simplified considerably. If the state of the fluid is independent of time at every point in space occupied by the fluid, the flow is called *stationary*. If the opposite is true, one has an *unsteady flow*. For stationary flows *Bernoulli's equation* holds, which says that the sum of the specific kinetic energy ($|\boldsymbol{v}|^2/2$) and of the enthalpy of the fluid is constant along a streamline. A *streamline* is defined as a curve whose tangent vector at each point of the curve has the same direction as the velocity field of the flow at that point.

If the fluid moves with a velocity smaller or larger than the sound speed, the flow is called *subsonic* and *supersonic* respectively. The Mach number $Ma \equiv |v|/c_s$, which is the ratio of the absolute value of the flow velocity $\boldsymbol{v}$ and the sound speed c_s, is the parameter characterizing this aspect of a flow. *Transonic flows* have $Ma \approx 1$. Supersonic flows accessible in the laboratory have Mach numbers $Ma \lesssim 10$, while astrophysical flows can be extremely supersonic ($Ma > 100$).

Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

When a flow accelerates (decelerates) from subsonic (supersonic) to supersonic (subsonic) speeds *shock waves* occur in the flow. A shock wave is a front across which there is a nearly discontinuous, finite jump in pressure, with corresponding jumps in temperature, density, and other fluid properties. Shocks are nonlinear waves whose behavior is much more complex than that of (linear) sound waves, which are periodic adiabatic pressure perturbations of the flow. Because of their nonlinear character linear superposition does not apply in shock wave interactions. Flows entering a shock at an oblique angle are deflected away from the normal direction. The deflection is due to a decrease of the normal component of the fluid velocity entering the wave. Hence kinetic energy is dissipated into heat in a shock wave, increasing the entropy of the fluid. Conservation of mass, momentum and energy must also hold across shock waves. This fact can be used to derive the *Rankine–Hugoniot relations* relating the fluid states on both sides of the shock wave.

One further discriminates between *viscous* and *inviscous* or *ideal* flows depending on the amount of viscosity of the fluid. The viscosity of a fluid varies, in general, with the thermodynamic state of the fluid. Except for superfluids the viscosity of a fluid is never exactly zero, but it may be sufficiently small to consider the fluid for all practical purposes as being inviscous or ideal. Quantitatively the viscous character of a fluid is determined by comparing the size of the viscous drag acting on the fluid with its inertia. The relevant flow parameter is the *Reynolds number* $Re \equiv |\boldsymbol{v}|l/\nu$, where l is a characteristic linear dimension of the flow, and ν is the kinematic viscosity of the fluid. Viscous flows have $Re < 1$. Most astrophysical flows have $Re \gg 1$ (Reynolds numbers larger than 10^{10} are not uncommon), because of the large size of the astrophysical objects.

A common feature of terrestrial and in particular of astrophysical flows is their tendency to undergo a spontaneous transition from *laminar* (i.e. smooth, regular type of flow) to *turbulent flow*. This occurs if the Reynolds number of the flow exceeds a critical value $Re_{\rm crit}$ beyond which effects due to inertia dominate over friction by such an amount that the flow becomes unstable to turbulence. From laboratory experiments one finds critical Reynolds numbers for fully developed turbulence in the range $1000 \lesssim Re_{\rm crit} \lesssim 2000$.

According to J O Hinze 'Turbulent fluid motion is an irregular condition of flow in which the various fluid quantities show a random variation with time and space coordinates, so that statistically distinct average values can be discerned'. Turbulent motion is not irregular in either space or time alone, but both. Turbulence can be generated by friction at fixed walls ('wall turbulence') or by flow of layers of fluids with different velocities past or over one another ('free turbulence'). In real viscous fluids, viscosity effects will result in the conversion of kinetic energy of flow into heat, i.e. turbulent flow is dissipative in nature. Hence, if there is no continuous input energy into the flow, the turbulent motion will decay. If the turbulence has quantitatively the same structure in all parts of the flow field, the turbulence is said to be *homogeneous*. If the statistical features have no preference for any direction, the turbulence is called *isotropic*. At a given point in the turbulent domain a distinct pattern is repeated more or less regularly in time, and at a given instant a distinct pattern is repeated more or less regularly in space. Turbulent motions in which distinct patterns can be discerned are described quantitatively by introducing the notion of *scale of turbulence*: a certain scale in time and a certain scale in space. Turbulent motion, in addition to its scale, is characterized by the violence or intensity of the turbulence fluctuations, which is defined by the root-mean-square value $w' \equiv \sqrt{w^2}$ of the random component $\boldsymbol{w}$ of the momentary value of the velocity $\boldsymbol{u} = \boldsymbol{v} + \boldsymbol{w}$ about the mean flow velocity $\boldsymbol{v}$. Often the intensity of the turbulence is defined by the *relative intensity* $w'/|\boldsymbol{v}|$.

Flow instabilities

Fluid flows are subject to a variety of flow instabilities, the most common ones being the buoyancy driven *Rayleigh–Taylor instability* and the *Kelvin–Helmholtz instability* occurring in shear flows.

Rayleigh–Taylor instabilities occur, for example, when two fluids of different densities are superposed one over the other or accelerated towards each other (see figure 1). According to a linear stability analysis the arrangement of two fluids is stable if the lighter fluid is on top of the heavier fluid. Otherwise the arrangement of fluids is unstable.

Rayleigh–Taylor instabilities are ubiquitous in astrophysical flows. A particular example is Rayleigh–Taylor instabilities induced by the propagation of a shock wave through the envelope of a massive star which explodes as a (core collapse) SUPERNOVA (see figure 2). Since the energy given to the shock wave in a supernova explosion is much larger than the binding energy of the mass outside the collapsed core, gravity is dynamically unimportant for the propagation of the shock wave through the stellar envelope. In this case the Rayleigh–Taylor instability is driven by pressure and density gradients of opposite signs, the 'effective acceleration' being the (negative) pressure gradient.

Kelvin–Helmholtz instabilities occur whenever the velocity field of the flow has a gradient perpendicular to the (local) flow direction, i.e. in the presence of shear flow. The Kelvin–Helmholtz instability gives rise to a roll-up of the shear layer. It is responsible for the formation of mushroom shaped flow structures seen, for example, in large atmospheric explosions, and in connection with Rayleigh–Taylor instabilities (see figures 1 and 2). In the latter case the rising bubbles and sinking spikes resulting from the Rayleigh–Taylor instability cause a shear flow with respect to the surrounding matter.

Fluid dynamics and nuclear burning

Much of our understanding of astronomy and astrophysics is inseparably connected to our understanding of fluid

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

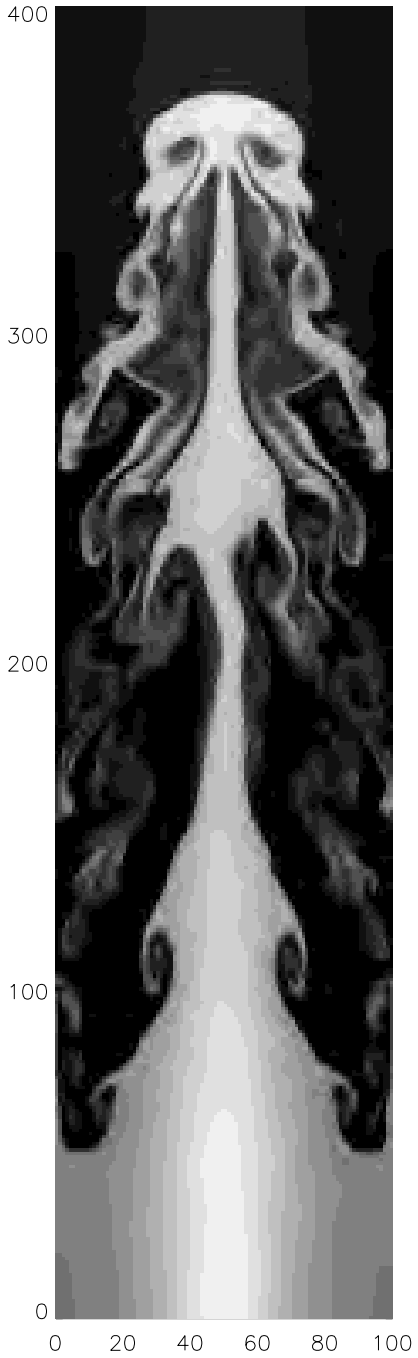

Figure 1. Rayleigh–Taylor instability in a dense fluid (bright) supported against gravity (directed upward!) by a lighter fluid (dark). The horizontal interface between the two fluids (initially located at 200) has been perturbed by a small sinusoidal perturbation. The typical structure of a narrow, high-density finger penetrating into the low-density region and a broader, low-density bubble at the edge of the grid penetrating into the high-density region is clearly visible. The mushroom cap structure on the top of the high-density region, which is created by the Kelvin–Helmholtz instability, is also apparent.

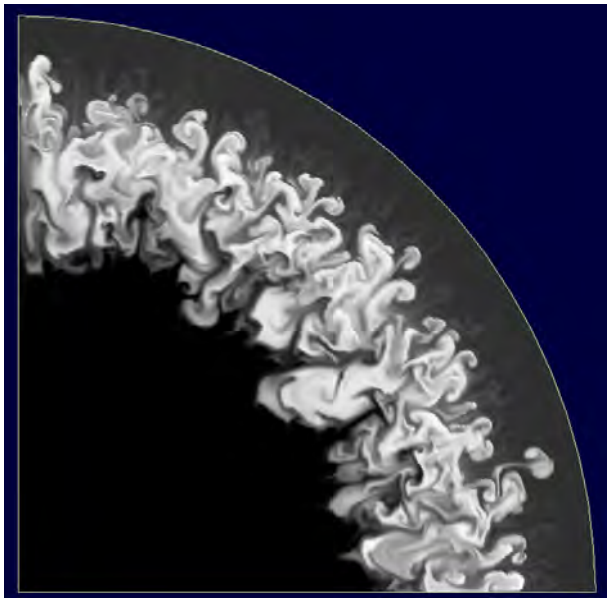

Figure 2. Simulation of Rayleigh–Taylor instabilities induced by the propagation of a shock wave through the envelope of a massive star which explodes as a (core collapse) supernova. The initially spherical helium shell (bright grey) of the progenitor star has been shredded by the instability. The snapshot is taken about 4 h after the onset of the explosion.

dynamics and nuclear burning. Thermonuclear processes and gravitational binding are the two major sources of energy for astronomical flows. The release of energy in an astrophysical PLASMA gives rise to changing pressure gradients and so to fluid motion. Such fluid motion, in turn, will transport ashes and fuel to and from the flame zone. This gives rise to a subtle and difficult problem. The degree of difficulty of the problem is closely related to the nature of the coupling between the nuclear burning and the fluid flow. Special cases, in which this coupling is simpler, can be treated more reliably. First, nuclear reactions release energy in the form of radiation and kinetic energy of particles; at stellar densities this energy acts to heat the medium in which the reactions occur. The heating can modify the pressure, and thereby modify the flow. Second, nuclear reactions change the composition of the material, which in turn may modify its equation of state and its opacity, which in turn may modify the pressure and the heating, and again the flow. Conversely, the flow may remove ashes and bring fuel to the flame, countering the natural tendency of the flame to exhaust its fuel.

Many different types of burning occur in astrophysical problems. Burning can range from quiet hydrostatic burning, such as occurs in the center of most stars, to the explosive burning which can occur, for example, in models of thermonuclear supernova explosions. Burning can occur in laminar or turbulent flows, the fluid motion being produced either by external causes and/or by the burning itself. Hence, the interaction between burning and flow

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

must be considered.

Hydrostatic burning is the least violent form of burning and occurs in stars that are hydrostatic. In this case, the reaction rate is slow enough that energy can be transported from the burning region by radiation or conduction as rapidly as it is generated. A similar case is a subsonically convective flame region, in which heat and ashes are removed by slow convection, and new fuel brought in.

Detonations are the most violent form of burning one encounters. Astrophysical detonations generally occur only under degenerate conditions. In its simplest form, detonation wave theory is easily understood. As a shock propagates into unburned fuel, it compresses and heats the material beyond the ignition point. Immediately behind the shock is the reaction zone, in which the fuel burns. In simple detonation theory the width of the reaction zone is neglected, and the detonation front is treated as a sharp discontinuity. In this case jump conditions can be derived for the change in the fluid variables across the front in much the same way as is done for a simple shock. Note, however, that in order to obtain the post-detonation state one must first choose a detonation velocity, because unlike the case for simple shocks, the front velocity is not determined from the jump conditions. The simple detonation theory assumes that the reaction rate is infinite and that the reaction zone has zero width. A slightly more complex treatment is used in the Zeldovich–von Neumann–Doering model. This theory assumes that the shock, which is taken to be infinitely thin, is followed by a reaction zone of finite width. The final state obtained after the fuel is completely burned is exactly the same as for the simpler theory described above.

Deflagrations represent a much less violent form of burning than detonations, but in many ways are more complex. They result when the burning is unable to produce sufficient overpressure to create a shock which is strong enough to ignite the fuel. The motion of the front is usually very subsonic. Burning is initiated by the diffusive transfer of heat from the hot ashes behind the front into the cold fuel. Although, for the case of a thin front, deflagrations must obey the same jump conditions as detonations, the propagation velocity now depends on the rate of heat transfer. Compared to detonations another major difference is that the pressure and density decrease behind the deflagration front, and in the reference frame in which the front is stationary, the velocity increases. In the simplest theory deflagrations are described as flow discontinuities, which propagate subsonically. If the flow is laminar, a physically more accurate description is that of a conductive or diffusive laminar flame, whose width and speed is determined by the rate of energy generation and the transport of energy and composition. In most situations, however, even this description is too simple, because deflagrations or subsonic flames are subject to a variety of instabilities, which can significantly influence their shape (wrinkling of the flame) and propagation speed. Moreover, because the propagation speed of the flame is subsonic, flame and flow do interact. In particular, if burning occurs in a convective or turbulent environment, depending on the relevant length scales and time scales, physically quite different combustion regimes must be considered.

Relativistic fluid dynamics

Some astrophysical phenomena require a relativistic formulation of fluid dynamics. A special relativistic formulation must be used if the flow velocity reaches a significant fraction of the speed of light, or if the internal energy of the fluid becomes comparable to its rest mass. Such conditions occur in jets from quasars, active galactic nuclei and some galactic compact binaries, and in gamma-ray burst sources. General relativistic flows involving strong gravitational fields and relativistic speeds are encountered in accretion flows onto compact objects like neutron stars or black holes, in the formation or merging process of neutron stars and black holes, and are most likely at the heart of the processes leading to the formation of relativistic jets and gamma-ray bursts.

An important difference between Newtonian and relativistic fluid dynamics is the presence of a maximum velocity, i.e. the speed of light in a vacuum in the latter case. A flow can be relativistic in two ways. In a kinematically relativistic jet the beam gas moves with relativistic velocity, while in a thermodynamically relativistic jet the specific internal energy of the beam gas is large compared with its rest mass energy.

Special relativistic astrophysical flows are encountered in extragalactic jets (see ASTROPHYSICAL JETS). These are highly collimated supersonic outflows from ACTIVE GALACTIC NUCLEI. Extragalactic jets are thought to be formed as a consequence of mass accretion onto a central rotating super massive BLACK HOLE in an active galactic nucleus being fed by interstellar gas and gas from tidally disrupted stars. Most models of the (initial) collimation and acceleration of astrophysical jets involve magnetohydrodynamic processes at or near the inner edge of a rotating magnetized accretion disk with corona. The combined action of thermal and magnetic pressure gradients, of centrifugal force and of gravity drives an outflow, which does collimate itself. General relativistic effects seem to be crucial for a successful launch of the jet. A Newtonian treatment of extragalactic jets is justified only at distances larger than several kiloparsec from the central black hole. At smaller scales, and in particular at parsec scales, jets propagate at relativistic speeds. Hence, special relativistic hydrodynamic simulations must be used in order to describe their propagation correctly (see figures 3 and 4).

Equations for ideal special relativistic flows

The equations of special relativistic fluid dynamics for an ideal fluid are most conveniently expressed as a set of conservation equations

$$\frac{\partial D}{\partial t} + \mathrm{div}(D\boldsymbol{v}) = 0$$

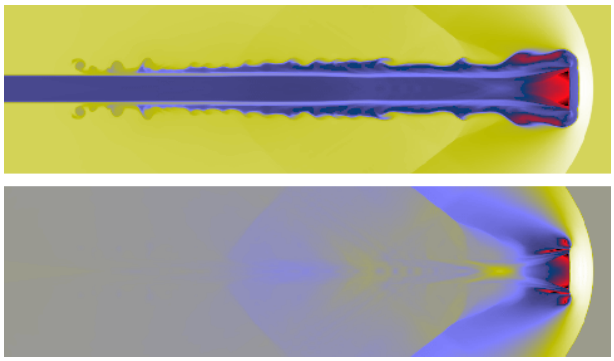

Figure 3. Color-coded contour plots of the logarithm of the proper rest-mass density (top) and pressure (bottom) of a hot, relativistic jet ($v_b = 0.99c$, $Ma = 1.72$). The maximum values are coded in white. Decreasingly smaller values are coded in green, bright blue, dark blue, red and the minimum values are coded in black. The jet has a 'naked' beam and almost completely lacks internal structure. The beam is surrounded by lobes (near the jet head) instead of a cocoon and is in pressure equilibrium with the shocked ambient medium. **This figure is reproduced as Color Plate 20.**

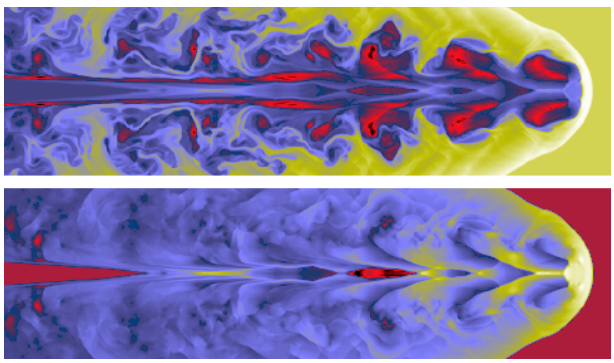

Figure 4. Same as figure 3, but for a cold, relativistic jet ($v_b = 0.99c$, $Ma = 6.0$). The jet has a beam with internal oblique shocks and an extended turbulent cocoon. **This figure is reproduced as Color Plate 21.**

$$\frac{\partial S^i}{\partial t} + \mathrm{div}(S^i \boldsymbol{v}) + (\mathrm{grad}\, p)^i = 0, \qquad i = 1, 2, 3$$

$$\frac{\partial \tau}{\partial t} + \mathrm{div}[(\tau + p)\boldsymbol{v}] = 0$$

for the conserved rest-mass density D, momentum density $\boldsymbol{S} = (S^1, S^2, S^3)$ and energy density τ, respectively. These variables, which are defined in a fixed frame, are related to quantities in the local rest frame of the fluid through

$$D = \rho W$$
$$\boldsymbol{S} = \rho h c^{-2} W^2 \boldsymbol{v}$$
$$\tau = \rho h W^2 - p - Dc^2$$

where ρ, p, $\boldsymbol{v}$, W, h and c are the proper rest-mass density, the pressure, the flow velocity, the flow Lorentz factor $W = (1 - v^2/c^2)^{-1/2}$, the specific enthalpy $h = c^2 + \varepsilon + p/\rho$, and the speed of light in a vacuum.

Numerical integration of the fluid dynamic equations

In astrophysical applications one usually has to solve the hyperbolic set of the inviscous and compressible Euler equations instead of the parabolic set of the viscous and compressible Navier–Stokes equations, because (except in shock waves) viscosity and heat conduction due to physical processes are often negligibly small. However, because of truncation errors and because of finite spatial resolution, all numerical methods proposed for the solution of the Euler equations possess some finite intrinsic numerical viscosity, whose form and size depends on the numerical method, on the grid resolution, and to some extent of the flow problem itself. The effect of the numerical viscosity on the solution can only be quantified by resolution studies, i.e. by performing a series of simulations of the same flow problem using different grid resolution. Thus, when simulating astrophysical flow one is in the strange situation that one tries to solve the inviscous Euler equations, but instead solves some viscous variant, which is also different from the Navier–Stokes equations.

The evolution equations are a set of coupled nonlinear first-order (in time) partial differential equations. One way of solving this set of equations is to discretize them in time and space. By this discretization the partial differential equations are transformed into a set of coupled nonlinear algebraic equations, which can be solved on a computer with appropriate numerical techniques. The algebraic equations are not uniquely determined, because a given differential equation can be discretized in different ways. Obviously, one tries to choose those algebraic systems which minimize the truncation errors, and which possess some additional properties, like being stable and consistent. This is at the heart of the 'art of computing'.

Guided by the conservation properties underlying the hydrodynamic equations applied mathematicians and physicists have been able to develop accurate and stable high-resolution finite volume schemes In finite volume schemes the (finite) computational domain is discretized into a finite number of zones or cells (typically 10^2 to 10^3 per spatial dimension). The hydrodynamic scalar fields (e.g. density) and the components of the vector fields (e.g. momentum) are approximated by a set of discrete values, which are the (approximate) cell averages of the respective variable. Time is discretized too, the evolution being approximated by a series of finite time steps (typically 10^3 to 10^5 per simulation).

Besides finite volume schemes, another completely different method is widely used in astrophysics for integrating the hydrodynamic equations. This method is smoothed particle hydrodynamics, or SPH for short. In SPH the fluid or gas is described by a finite set of 'particles' (typically 10^3 to 10^5), which move with the flow. SPH is a free-Lagrange method, in which spatial gradients are evaluated without the use of a grid.

Bibliography

The literature on fluid dynamics is extensive. Thus, the following references can only provide entry points into the field.

The derivation of the fluid dynamic equations using the phenomenological approach can be found, for example, in the book by

Shu F H 1991 *The Physics of Astrophysics* (Mill Valley, CA: University Science Books)

The kinetic theory approach to the equations of fluid dynamics is described in detail by

Hirschfelder J O, Curtiss C F and Bird R B 1964 *Molecular Theory of Gases and Liquids* (New York: Wiley)

A general introduction to fluid dynamics can be found in

Landau L D and Lifshitz E M 1982 *Course of Theoretical Physics, Vol.VI, Fluid Mechanics* (Oxford: Pergamon)

For a modern description of numerical techniques for the solution of the equations of fluid dynamics one can consult, e.g.

Laney C B 1998 *Computational Gasdynamics* (Cambridge: Cambridge University Press)

or with special emphasis on astrophysical fluid flow including also various astrophysical applications

LeVeque R J, Mihalas D, Dorfi E A and Müller E 1998 *Computational Methods for Astrophysical Fluid Flow* ed O Steiner and A Gautschy (Berlin: Springer)

Flux Density

A measure of the radiation arriving from a source at a particular frequency. The *flux* of radiant energy is the quantity of energy per second (watts) passing through unit surface area (1 meter squared) perpendicular to the direction of the source and expressed as W m^{-2}. The flux density is the flux of radiant energy within a unit interval of frequency (a frequency band with a width of 1 hertz) and is expressed as W m^{-2} Hz^{-1}.

The flux densities for most cosmic radio sources are extremely low. A unit of flux density used by radioastronomers is the jansky (Jy), where 1 Jy = 10^{-26} W m^{-2} Hz^{-1}.

Focal Length

The distance between the center of a lens, or the reflective surface of a mirror, and its focal point, or focus (the point at which rays of light from a point source, located effectively at an infinite distance, converge to form an image).

See also: focal ratio, mirror, objective lens.

Focal Ratio

The ratio of the focal length of a lens or mirror to its aperture. For a lens or mirror of focal length, F, and aperture, D, the focal ratio, f, is given by $f = F/D$. For example, a lens of 10 m focal length and 2 m aperture would have a focal ratio of $10/2 = 5$; this would be written as 'f:5'.

The focal ratio, or f-number, of a camera lens may be altered by means of an adjustable diaphragm that changes its aperture. For a lens or mirror of given focal length, increasing the aperture (and thereby reducing the focal ratio) increases the illumination of the image. Because, in general photography, this decreases the exposure time that is needed in order to record a particular image, the term 'focal ratio' is synonymous with the 'speed' of an optical system (for example, an f:2 system is faster than an f:16 system).

See also: aperture, focal length.

Focus

(1) In optics, the point at which parallel light rays from a distant point source are brought together by a lens or mirror to form an image. Light rays traveling parallel to the optical axis (the line that passes perpendicularly through the center of a lens or mirror) of an ideal convex lens or concave mirror converge to intersect at the focus, or focal point, of the lens or mirror. Rays arriving at an angle to the optical axis, from point sources or extended objects (sources of finite angular size), form images at the focal plane, a plane that passes through the focal point perpendicular to the optical axis. In practice, the focal plane may be slightly curved.

In a conventional refractor, light is brought to a focus by the objective lens, the distance between the objective and the focus being the focal length. In a reflecting telescope, the focal point of light rays reflected from the primary mirror (the mirror that collects incoming light) is called the prime focus. Instrumentation, or even an observer, may be placed directly at the prime focus of a large reflector. Most reflecting telescopes use one or more additional mirrors to reflect the converging cone of light, and the focal point, to a different location. In the Newtonian reflector, a small flat mirror, set at an angle of 45° to the optical axis, reflects the converging cone of light to a focal point (the Newtonian focus) at the side of the telescope tube. In the Cassegrain system, a convex secondary mirror, located a short distance before the prime focus, changes the angle of convergence of the rays and reflects light back through a central hole in the primary to the Cassegrain focus. Because of the magnifying effect produced by their curved secondaries, Cassegrain and related systems have effective focal lengths that are several times longer than the focal length of their primary mirrors.

In the Nasmyth system, which can be used with telescopes on altazimuth mountings, light reflected from a convex secondary passes back down the telescope tube and is then reflected from a flat tertiary (third), through a hollow altitude axis (the axis round which the telescope turns in elevation), to a focus (the Nasmyth focus) that remains in the horizontal plane no matter in what direction the telescope itself is pointing. In the coudé system, which may be used with equatorially mounted telescopes, light reflected from a convex secondary is then reflected from a plane tertiary mirror to a plane quadric (fourth) mirror which, in turn, reflects light down the polar axis of the mounting to a fixed focal position—the coudé focus.

See also: altazimuth mounting, Cassegrain telescope, equatorial mounting, mirror, Newtonian telescope, objective lens, reflector, refractor.

(2) In an ellipse, a focus (plural: foci) is one of two points on the major axis such that the sum of the distances from each of the two foci to any point on the ellipse is a constant.

See also: conic sections, ellipse.
